DIFFERENTIAL DIAGNOSIS

Definition

Follicular helper T-cell (TFH) lymphomas are nodal, mature T-cell lymphomas that share immunophenotypic features and the gene-expression signature of TFHs,[1] a specialized subset of T cells that constitute a component of secondary lymphoid follicles and that are essential for the formation of germinal centers, affinity maturation, and development of high-affinity antibodies.[2,3] The revised WHO 4th ed. created an umbrella category of "nodal lymphomas of TFH origin" encompassing three entities: angioimmunoblastic T-cell lymphoma (AITL), follicular T-cell lymphoma, and peripheral T-cell lymphoma (PTCL) with TFH phenotype, the latter characterized by a diffuse pattern and lack of follicular dendritic cell (FDC) expansion.[4,5] A TFH phenotype is defined by the expression of two or more TFH-associated immunophenotypic markers including PD1, ICOS, CXCL13, CD10, and BCL6.[6] In addition to these markers, CXCR5, SAP, c-MAF, and CD200 can also be used for diagnostic purposes.[7-10]

TFH lymphomas, in addition to sharing a TFH immunophenotype, are unified by a common gene-expression profile (GEP) and genetic landscape.[11-13] For these reasons, the International Consensus Classification (ICC) proposed to consider all nodal/systemic lymphomas of TFH derivation as a single entity, namely "follicular

helper T-cell lymphoma" (TFH lymphoma) with three morphologic subtypes: angioimmunoblastic type (AITL), follicular type, and not otherwise specified (NOS) (**Table 35-1**).[14] By definition, primary cutaneous small/medium CD4-positive T-cell lymphoproliferative disorder (LPD) or other cutaneous lymphomas with TFH phenotype are excluded.[15] The criteria to discriminate among the three TFH subtypes remain the same as in the revised WHO 4th ed. and are based mainly on morphology, lymph node architecture, microenvironment, and distribution of FDCs.[4,5] Nevertheless, the different subtypes may show considerable plasticity, both within the same patient at diagnosis and between the diagnostic sample and relapses.[16,17] Because the mutational landscape of TFH lymphomas is so characteristic, especially of AITL, mutations in *RHOA*^{G17V} and *IDH2*^{R172} are valuable in supporting the diagnosis of TFH lymphoma.[13] Additionally, loss-of-function mutations in *TET2* or *DNMT3A* suggest that TFH lymphomas, mainly AITL, in many instances, develop on a background of clonal hematopoiesis.[18]

Synonyms and Related Terms

The revised WHO 4th ed. created an umbrella category of "nodal lymphomas of TFH origin" encompassing three entities: angioimmunoblastic T-cell lymphoma (AITL), follicular T-cell lymphoma, and peripheral T-cell lymphoma (PTCL) with TFH phenotype, the latter characterized by a diffuse pattern and lack of follicular dendritic cell (FDC) expansion.[4,5]

The WHO 5th ed. retained the concept of three, yet closely related, entities under the umbrella term of "nodal T-follicular helper cell

lymphomas (nTFHL)": nTFH, angioimmunoblastic lymphoma-type, nTFH, follicular lymphoma type and nTFH, NOS.[19]

Epidemiology

AITL accounts for approximately 1% to 2% of non-Hodgkin lymphomas (NHL). It is the most common specific subtype of PTCL worldwide, representing roughly 36% of noncutaneous PTCL.[20] AITL is most frequently observed in middle-aged and older adult patients, with a peak incidence in the 6th and 7th decades of life, although young adults may rarely be affected.[21] It has been reported to be slightly more frequent in males than females and appears to be more prevalent in Europe (29% of PTCL cases)[22] than in North America or Asia, where the prevalence is approximately 16% to 18% of cases.[23]

Table 35-1

EBV, Epstein-Barr virus; *FDC,* follicular dendritic cell; *HEV,* high endothelial venules; *PTGC,* progressive transformation of germinal centers; *TFH,* T-cell follicular helper.

In contrast, both TFH lymphomas of follicular type and NOS are rare. TFH lymphoma, follicular type accounts for 2% to 2.5% of noncutaneous PTCL.[24] Patients have a median age of onset of 60 to 65 years, and there is a slight male predominance.[16,25-27] Since its definition has changed over the years, no exact data are available regarding the true incidence of TFH lymphoma, NOS, nor is there reliable information on geographic distribution or gender predominance.

Etiology

The cause of TFH lymphomas is unknown. Originally AITL, the protype of the group, was speculated to be triggered by the administration of drugs, or to occur after an infectious disease, suggesting that AITL represented the manifestation of an abnormal immune reaction.[28] Subsequent work explored the role of Epstein-Barr virus (EBV) in the pathogenesis of AITL. EBV has been detected by in situ hybridization in 80% to 96% of lymph nodes involved by the disease.[29] In most cases, the EBV-infected cells represent transformed B cells. The prevalence of infected B cells in AITL lymph nodes ranges from 1 in 10 to 1 in 500 B cells in lymph nodes.[30] In contrast, in healthy EBV carriers, EBV resides in B cells at a frequency of approximately 1 in 10^6 to 1 in 10^7. Despite the obvious pathogenetic role of EBV in a variety of other lymphomas, the presence of EBV in AITL most likely reflects the underlying immunodeficiency inferred by and characteristic of the neoplastic process.

Follicular Helper T Cells

TFH cells are a distinct functional subset of effector T-helper cells residing in the germinal center that are specialized in providing help to B cells during the germinal center reaction.[31] TFH cells promote B cell survival, formation of germinal centers, immunoglobulin class-switch recombination, and somatic hypermutation, ultimately yielding high-affinity plasma cells and memory B cells.[32] TFH differentiation is dependent on the transcriptional repressor BCL6 and the expression of CXCR5, which are first detectable in T cells at the border between the T-zone and the follicle (T/B zone border)

soon after T-cell priming and before germinal-center formation.[33,34] BCL6 expression in T cells is able to downregulate CCR7 and upregulate CXCR5 inducible costimulator (ICOS), programmed death 1 (PD1), interleukin (IL)-21R, and IL-6R. The expression of ICOS also seems to play an important role in the initial stage of TFH differentiation at the time of T-cell priming by antigen-presenting dendritic cells.[35] These CD4-positive, CXCR5-positive, BCL6-positive T cells, so called "pre-TFH cells," are essential for the initiation of the germinal center and extrafollicular antibody responses.[33] The TFH-specific secretory profile, including IL-21, CXCL13 chemokine, and its receptor CXCR5, are critical to recruit and localize TFH cells in the germinal center. CXCR5 enables the migration of TFH cells into CXCL13-rich areas in B-cell follicles. Once TFH cells are located in the germinal center, they upregulate the expression of PD1, IL-21, CD84, and ICOS. These markers, which are characteristic of TFH cells, can be used in diagnostic practice either by flow cytometry or by immunohistochemistry on routinely formalin-fixed tissue.

Clinical Features

The clinical presentation of AITL is unique among malignant lymphomas, and the diagnosis is frequently suspected on clinical grounds. Most patients present with generalized peripheral lymphadenopathy, hepatosplenomegaly, and prominent systemic symptoms including fever, weight loss, and rash, often with pruritus.[36] One-third of patients present with edema, especially in the upper extremities and face; pleural effusion; arthritis; and ascites. A pruritic maculopapular rash can be seen. The bone marrow

is commonly involved.[37] Approximately 30% of patients present with eosinophilia, and 10% with plasmacytosis.[38] Polyclonal hypergammaglobulinemia and Coombs-positive hemolytic anemia are frequently present. Laboratory studies may reveal the presence of cold agglutinins, circulating immune complexes, anti–smooth muscle and antinuclear antibodies, positive rheumatoid factor, and cryoglobulins. The evolution of the disease is often complicated by intercurrent infections with conventional and opportunistic microorganisms. There is no consensus regarding the best therapeutic approach to patients with AITL. However, recent studies suggest that TFH lymphomas respond better to histone deacetylase and DNA methyltransferase inhibitors because of the common alterations in epigenetic modifying genes identified in this disease.[39,40]

Patients may respond initially to steroids or mild cytotoxic chemotherapy, but progression usually occurs. Derivation from TFH cells explains many of the distinctive clinical characteristics of AITL, including hypergammaglobulinemia, autoimmune phenomena, and clonal B-cell proliferations, suggesting that the malignant TFH cells, like their normal counterparts, can stimulate B-cell proliferation. Clinical features of TFH lymphoma, follicular type seem to be similar to those of AITL. Advanced stage disease and systemic lymphadenopathy are common, and skin manifestations may occur. Autoimmune phenomena such as polyclonal hypergammaglobulinemia and positive direct Coombs test have been reported.[13,16,25,27,41] Rare data on TFH lymphoma, NOS suggest a similar spectrum of clinical manifestations.[13]

Morphology

Follicular Helper T-Cell Lymphoma, Angioimmunoblastic Type

In contrast to the other PTCL, NOS, AITL displays some unique morphologic features in involved lymph nodes (**Box 35-1**).[42] At low magnification, the lymph node architecture is usually effaced. There is a polymorphic infiltrate of small-to-medium-sized lymphocytes intermingled with granulocytes, eosinophils, plasma cells, fibroblast-like dendritic cells, histiocytes, and epithelioid cells predominantly occupying the paracortical or interfollicular area (**Fig. 35-1**). Often, the neoplastic T-cell population is obscured by a large number of inflammatory cells, but, occasionally, a neoplastic T-cell population can be readily identified on morphologic grounds. In these cases, there is an infiltration of atypical T cells characterized by round to irregular nuclear contours and sometimes broad, clear cytoplasm with distinct cell membranes (clear cells) (**Fig. 35-2A**). Cytologic atypia of the lymphoid cells, although frequently observed, is not a prerequisite for the diagnosis (see **Fig. 35-2B**). The proportion of atypical T cells may vary greatly from small foci to large confluent sheets, sometimes posing problems in the differential diagnosis with TFH lymphoma, NOS or PTCL, NOS. It is noteworthy that medium-to-large-sized basophilic blasts of B-cell phenotype may be present, some of them reminiscent of Hodgkin cells (**Fig. 35-3**).[42]

The vast majority of AITL cases display a pronounced proliferation of FDCs localized outside the residual follicles, typically abutting the high endothelial venules (HEVs). Occasionally, remnants of follicles with concentrically arranged, onion-shaped FDC meshworks are present, giving them a burned-out appearance (Fig. 35-4). In less

obvious cases, FDC proliferation may be recognized only after immunohistochemical staining with antibodies directed against CD21, CD23, or CD35 antigens. Another diagnostic feature of the disease is the extension of the infiltrate beyond the lymph node capsule into the perinodal fat, frequently sparing preserved cortical sinuses that appear to be "jumped over" by the tumor cells (**Fig. 35-5**). A key feature is the presence of numerous, frequently arborizing, postcapillary HEVs, which are also seen outside the lymph nodes in the perinodal infiltrate. The HEVs are best recognized in silver stains, such as Gomori silver impregnation, or in periodic acid–Schiff stains, highlighting both the conspicuous angioarchitecture and the thickened, hyalinized basement membranes of vessel walls (**Fig. 35-6**). Three major morphologic patterns are recognized.[43] In pattern 1 (20% of cases), the lymph node architecture is preserved, with hyperplastic germinal centers (**Fig. 35-7A**). Pattern 2 (30% of cases) is characterized by the loss of normal architecture and the presence of occasional depleted follicles or "burned-out" germinal centers, sometimes mimicking Castleman disease (see **Fig. 35-7B–C**). In pattern 3 (50% of cases), the normal architecture of the lymph node is completely effaced, and no B-cell follicles are present. These patterns seem to represent different morphologic stages of the disease, with consecutive biopsies from the same patient showing a transition from pattern 1 to pattern 3, which is thought to represent morphologic evolution rather than clinical progression of the disease.[17]

Box 35-1 Diagnostic Criteria for Follicular Helper T-Cell Lymphoma, Angioimmunoblastic Type (AITL)

Morphology

- Usually effaced lymph node architecture
- Perinodal extension of infiltrate, with sparing of sinuses
- Polymorphic infiltrate of lymphocytes, granulocytes, plasma cells, and immunoblasts
- T cells with abundant clear cytoplasm (clear cells)
- Proliferation of FDCs
- Proliferation of arborizing high endothelial venules

Immunophenotype

- Demonstration of FDC networks CD21 positive, CD23 positive
- $CXCL13^+$, $ICOS^+$, $PD1^+$, $CD10^+$, $BCL6^+$, $CD4^+$ neoplastic T cells
- CD3 positive, CD5 positive, CD4 ≫ CD8 with no T-cell antigen loss
- EBV-positive B blasts

Molecular Genetics

- TR gene clonally rearranged in 75% of cases (range, 70%–90%)
- IG genes clonally rearranged in 12% of cases (range, 10%–20%)
- TFH molecular signature

- Frequent mutations in *TET2, RHOA, IDH2, DNMT3A* genes
- Rearrangements in *VAV1, ICOS::CD28*
- Cytogenetics
    - Clonal chromosome aberrations in 89%
    - +3, +5, additional X chromosome

EBV Positivity

- 50% to 97% of cases by in situ hybridization
- EBER-positive B cells and rarely T cells

EBER, EBV-encoded small RNA; *EBV,* Epstein-Barr virus; *FDC,* follicular dendritic cell; *IG,* immunoglobulin genes; *TR,* T-cell receptor; *TFH,* follicular helper T cell.

Pattern 1 is the most difficult to recognize morphologically. The lymph nodes show a largely preserved architecture with hyperplastic follicles mimicking a reactive condition. A clue to the diagnosis is the absence of well-formed mantle cuffs (**Fig. 35-7D**). There are well-structured (hyperplastic) germinal centers with poorly developed mantle zones and sometimes ill-defined borders, so-called naked germinal centers (see **Fig. 35-8A**).[44] The specific morphologic alterations are confined to the perifollicular area where a rim of atypical clear cells is observed (**Fig. 35-8A**). The tumor cells are best recognized upon immunohistochemistry because of their strong CD10 and PD1 reactivity in aberrant localization (**Fig. 35-8C**). AITL pattern 1 lacks the FDC expansion characteristic of the disease (**Fig. 35-8B**). The presence of CD4-positive T cells (see **Fig. 35-8E**) with aberrant expression of TFH markers CD10, BCL6, PD1, CD278, CXCL13, or others in the outer rim of the germinal centers and

paracortex has been described as an important diagnostic feature (**Fig. 35-8C–E**).[43] If this "early" pattern is suspected, evidence of a clonal expansion of T cells by analyzing the T-cell receptor (TR) gene rearrangement configuration or finding characteristic gene mutations should be sought, and clinical features should be compatible with the diagnosis. Despite morphologically "early" involvement, the patients usually have clinically systemic, advanced disease. In subsequent biopsies, some of these cases may show progression to typical AITL with effaced nodal architecture.[17] Pattern 2 is characterized by depleted follicles. In contrast to pattern 1, there is expansion of FDCs as demonstrated by CD21 or CD23 usually extending from the depleted, atrophic follicles. The CD4-positive, PD1-positive, ICOS-positive cells are embedded in the meshworks of FDCs (**Fig. 35-9A–D**).

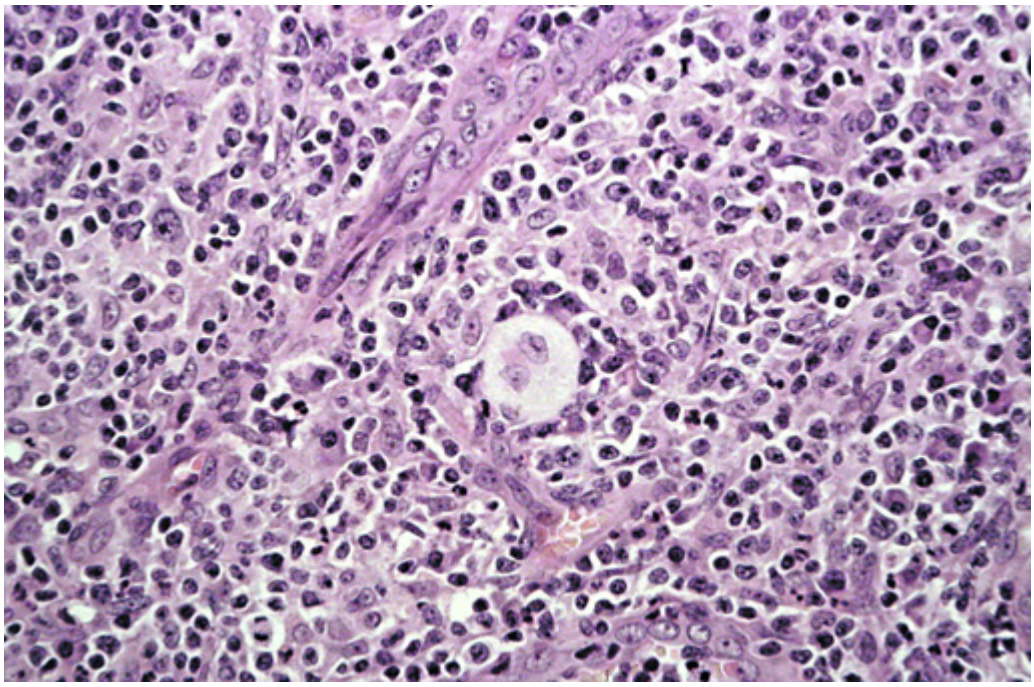

FIGURE 35-1 Typical morphology of follicular helper T-cell lymphoma, angioimmunoblastic-type (AITL). There is a polymorphic infiltrate of small-to-medium-sized lymphocytes with clear cytoplasm intermingled with eosinophils, plasma cells, fibroblast-like dendritic cells, histiocytes, and epithelioid cells.

Outside of lymph nodes, the most common sites of involvement are bone marrow and skin. Skin biopsies often show mild perivascular or periadnexal lymphoid infiltrates that are difficult to differentiate from inflammatory conditions.[45,46] In some cases, the cutaneous infiltrates may show the characteristic phenotype of AITL, with aberrant expression of CD10.[17,47] TR rearrangement is identified in more than 80% of the cases and usually is identical to the pattern found in lymph nodes.[45,46] However, it is unlikely that a primary diagnosis can be made based on a skin biopsy alone.

Bone marrow involvement is characterized by single or multiple loose nodular infiltrates with a paratrabecular or interstitial distribution pattern. The infiltrate is usually polymorphic in composition similar to that seen in lymph nodes.[48,49] Aberrant expression of CD10 or strong PD1 expression might be useful in the diagnosis.[50,51] The most frequent aberrations identified in peripheral blood by flow cytometry include loss of surface CD3, CD4 positivity together with altered T-cell receptor expression, and aberrant CD10 expression.[52] AITL may be associated with marked splenomegaly, but splenectomy is not indicated. Because AITL is usually a systemic disease, the characteristic infiltrates may be seen in other sites of involvement, including the liver and lung.

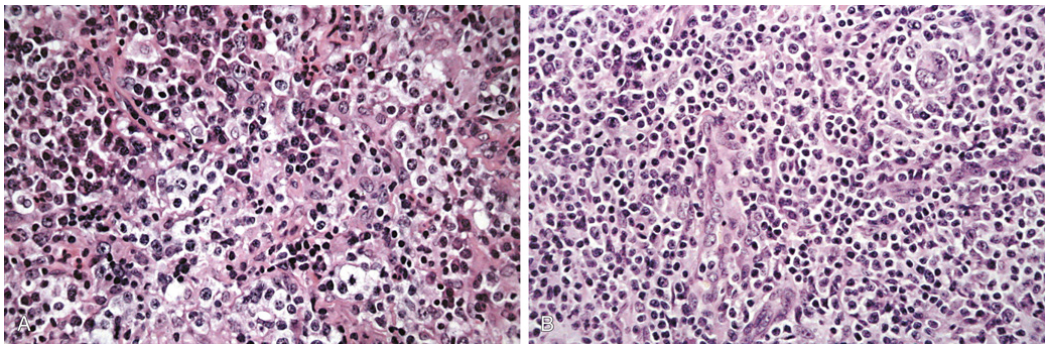

FIGURE 35-2 Cytologic spectrum of neoplastic T cells in follicular helper T-cell lymphoma.A, The infiltrate is composed of atypical T cells characterized by irregular nuclear contours and broad, clear cytoplasm with distinct cell membranes (clear cells). **B,** The neoplastic T cells are small to intermediate in size, with no atypia and a clear cytoplasm. Note the presence of a Reed-Sternberg–like cell.

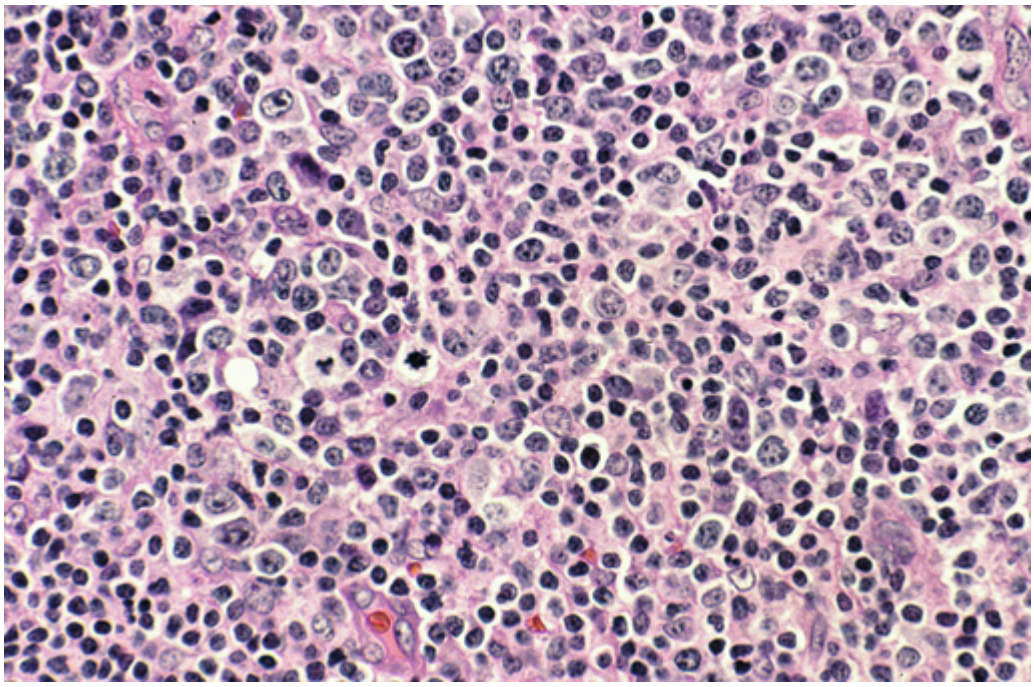

FIGURE 35-3 Large B-cell blasts. Intermingled with the neoplastic T cells are medium-to-large-sized basophilic blasts of B-cell phenotype, some of them reminiscent of Hodgkin cells.

Abundant Epithelioid Histiocyte Reaction

Some cases of AITL may show a prominent admixture of epithelioid cells, obscuring the diagnostic morphologic features of the disease (**Fig. 35-10A**). In these cases, the diagnosis relies on the presence of classical criteria such as arborizing HEVs and proliferating FDCs, in contrast to epithelioid cell–rich classic Hodgkin lymphoma (CHL) (containing classic Hodgkin and Reed-Sternberg [HRS] cells) and the lymphoepithelioid variant of PTCL, NOS (Lennert lymphoma), in which these features are lacking.[53]

Sheets of Small-to-Large Neoplastic T Cells ("Tumor Cell Rich")

In some cases, the neoplastic T-cell population becomes unusually predominant, forming sheets of small-sized or medium-to-large-sized cells and obscuring the "inflammatory" background infiltrate commonly present in AITL (see **Fig. 35-10B**).[54] This pattern may be especially seen at relapse, possibly representing disease progression and sometimes fulfilling criteria of TFH lymphoma, NOS; however, as long as the diagnostic features are still recognizable (e.g., hypervascularity, perinodal extension, and especially FDC proliferation), a diagnosis of tumor cell–rich AITL may still be rendered.[13,54]

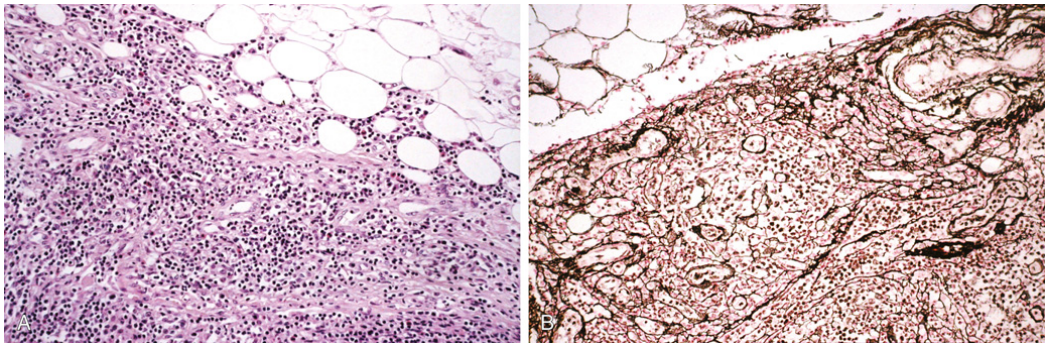

FIGURE 35-5 Extension of the infiltrate beyond the capsule.A, Infiltration into the fat, with preservation of the cortical sinuses that appear to be "jumped over" by the tumor cells. **B,** Gomori stain highlights the presence of open cortical sinuses, a diagnostic feature of angioimmunoblastic T-cell lymphoma.

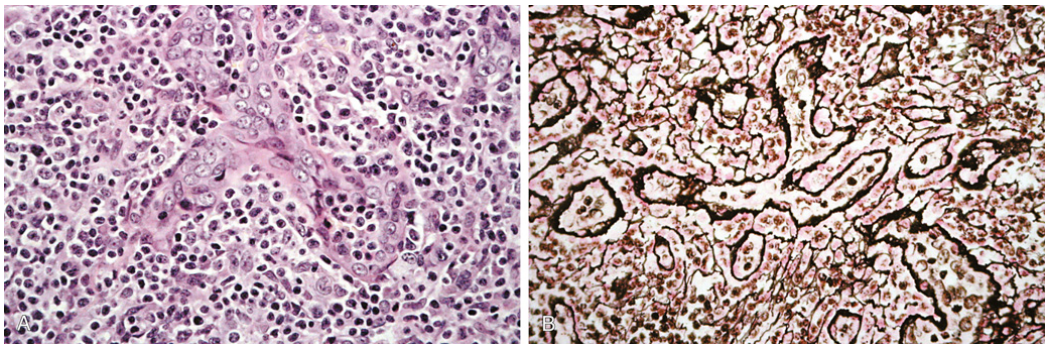

FIGURE 35-6 **A,** Arborizing high endothelial venules (HEVs). **B,** Gomori stain highlights the presence of arborizing HEVs, a characteristic finding in angioimmunoblastic T-cell lymphoma.

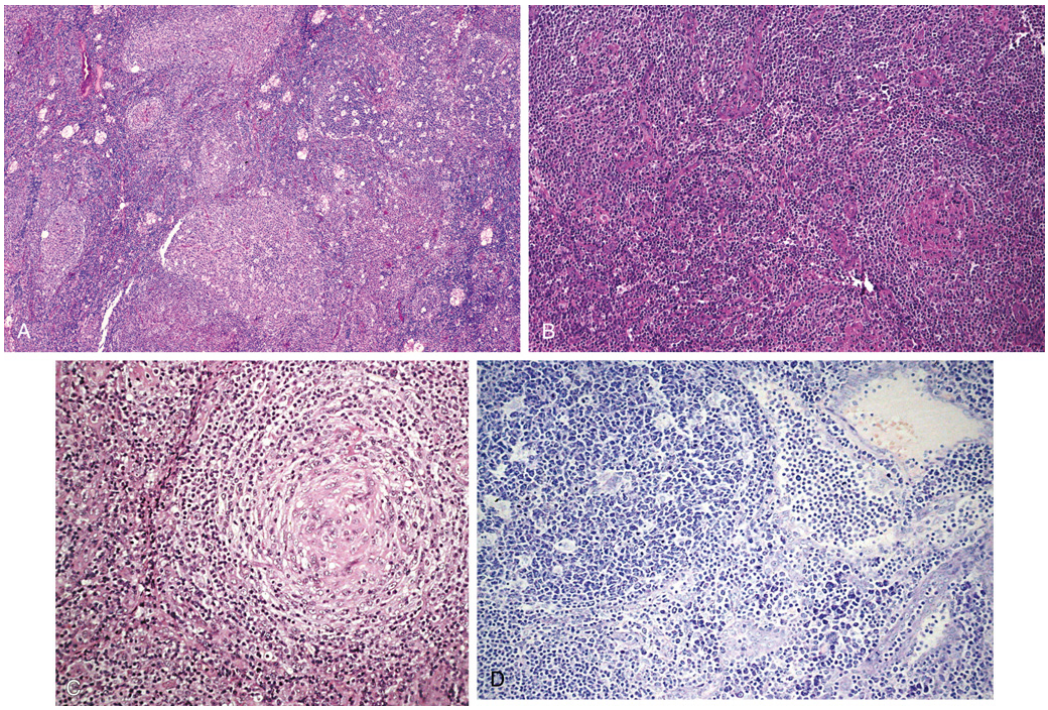

FIGURE 35-7 Histologic patterns of follicular helper T-cell lymphoma, angioimmunoblastic type.A, Early case with hyperplastic follicles without a mantle zone and an expanded paracortical area (pattern 1). **B,** Case with "burned-out" germinal centers, reminiscent of Castleman disease, with paracortical expansion and proliferation of arborizing high endothelial venules (pattern 2). **C,** Higher magnification of a depleted, atrophic follicle with clear proliferation of follicular dendritic cells (pattern 2). **D,** Giemsa stain of a hyperplastic follicle with absence of a mantle zone and an expanded paracortical area (pattern 1).

Follicular Helper T-Cell Lymphoma, Follicular Type

TFH lymphoma, follicular-type shows a proliferation of T cells expressing a TFH phenotype arranged in a follicular growth pattern (**Fig. 35-11A–C**). HEVs and proliferations of FDCs characteristic of AITL are absent.[14,19,55]

TFH lymphoma, follicular type affects lymph nodes, and systemic disease is common. Extranodal sites of involvement include skin, liver, spleen, and bone marrow. The clinical features of TFH lymphoma, follicular type are similar to those of AITL. TFH lymphoma, follicular type is a rare disease based on few studies available, with a median onset at 60 years and a slight male predominance.[16,25-27]

TFH lymphoma, follicular type shows effacement of the underlying nodal architecture, and a nodular or follicular proliferation of medium-sized tumor cells with often clear cytoplasm and round or slightly irregular nuclei. These neoplastic cells may be organized in well-defined nodules/follicles or in a pattern that is similar to that seen in progressively transformed germinal centers (PTGC), displaying aggregates of neoplastic cells that are surrounded by small lymphocytes of mantle zone type.[16,55] These patterns can also occur simultaneously. In some cases, areas of follicular type overlap with areas of AITL.[16,41,54] Furthermore, in relapsed disease, patterns may change and follicular type may relapse as AITL morphology or vice versa.[16,17] Scattered large, transformed cells can be interspersed and HRS-like cells are often found in the small cellular background in the PTGC-like pattern.[56]

Staining for FDC markers often discloses slightly expanded FDC meshworks confined to the nodular proliferations seen in

conventional morphology. The scattered large cells may be EBV positive.[16] In the PTGC-like pattern, IgD-positive small B cells of mantle zone type encircle clusters of neoplastic T cells.[16] Of note, the HRS-like cells seen in the PTGC-like pattern are often CD30 positive, and show variable expression of CD15, EBV, and B-cell antigens; they are surrounded by neoplastic T cells with a TFH phenotype. These features can lead to an erroneous diagnosis of CHL.[56] The differential diagnoses comprise follicular lymphoma (FL) and CHL in cases with (prominent) admixture with HRS-like cells.

Follicular Helper T-Cell Lymphoma, Not Otherwise Specified

TFH lymphoma, NOS is a primarily node-based PTCL with a TFH immunophenotype, which does not exhibit diagnostic characteristics of AITL or TFH lymphoma, follicular type.[14] Because this morphologic variant was first recognized in the revised 2017 WHO 4th ed., there are no reliable data on the true incidence of this subtype.[5]

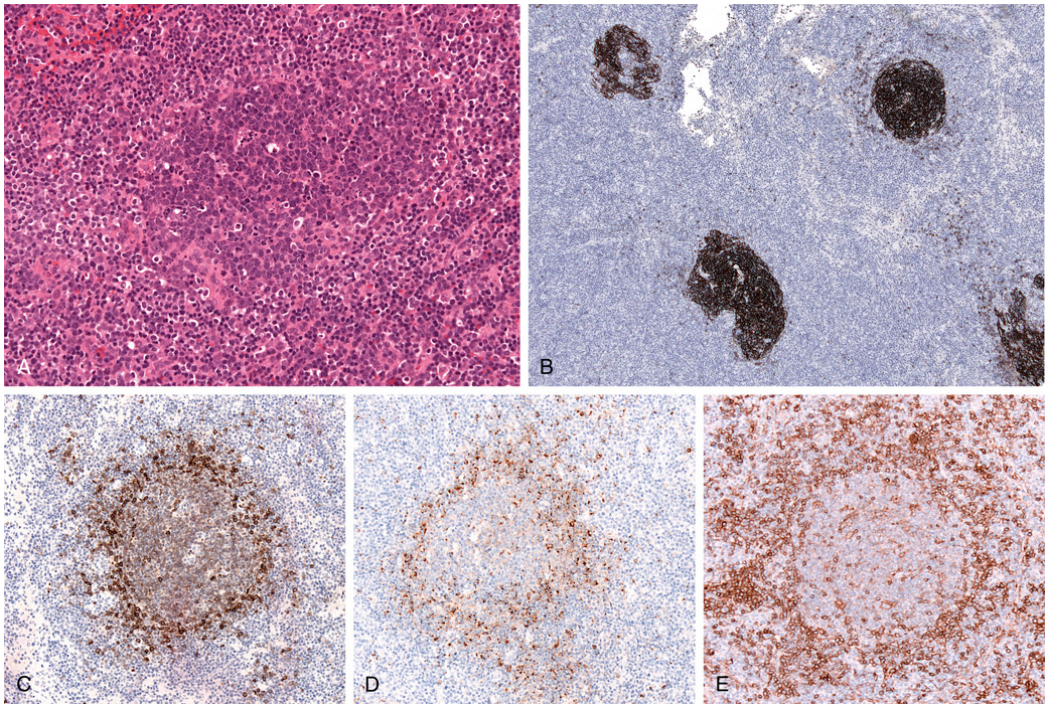

FIGURE 35-8 Follicular helper T-cell lymphoma, angioimmunoblastic-type with "naked" hyperplastic germinal centers (pattern 1).A, Hyperplastic follicle without a mantle zone and clear cells surrounding the germinal center. **B,** CD23 showing the normal follicular dendritic cells meshwork without expansion. **C,** CD10 is weakly positive in the normal germinal center cells and strongly positive in the tumor cells surrounding the germinal center. CXCL13 **(D)** and CD4 **(E)** are positive in the same cells.

Similar to AITL, TFH lymphoma, NOS clinically presents as a systemic nodal disease with autoimmune phenomena such as Coombs-positive hemolytic anemia.[13] Microscopically, the preexisting architecture of the lymph nodes is usually effaced, and

there is a diffuse infiltrate of medium-to-large-sized lymphoid cells forming sheets. The inflammatory background, hyperplasia of HEVs, and extrafollicular FDC expansion characteristic of AITL are absent. The latter feature is particularly important because lack of FDC expansion separates TFH lymphoma, NOS from rare cases of AITL with tumor cell–rich or anaplastic features. In some instances, the B-cell follicles are preserved, thus creating a main pattern of involvement in the T zone.[57]

B-Cell Lymphoproliferation or B-Cell Lymphoma

Studies have reported that more than 80% of AITL cases contain a variable number of EBV-positive B cells.[58-61] There is clear evidence that large B-cell lymphomas may arise in TFH lymphomas, mainly described in AITL. These large B-cell lymphomas may be present at initial diagnosis or develop over time. In the majority of cases, an EBV infection triggers the B-cell lymphoproliferation, which in turn is fostered by the profound immunodeficiency associated with the disease and possibly by the additional immunosuppression induced by chemotherapy.[61] EBV-associated B-cell lymphoproliferations in AITL constitute a spectrum of alterations.[62] The histologic picture in these cases is characterized by the presence of large EBV-positive B blasts in an otherwise typical TFH lymphoma (**Fig. 35-12A**). These blasts may have the appearance of immunoblasts or bear a resemblance to HRS cells; they may be focally accentuated or diffusely scattered, or they may form confluent sheets indistinguishable from diffuse large B-cell lymphoma.[60] These B-blasts are usually EBV-encoded small RNA (EBER) positive, CD20

positive, CD30 positive, CD15 negative, and latent membrane protein-1 (LMP-1) positive or negative (see **Fig. 35-12B–D**).[61]

AITL is often associated with polyclonal plasmacytosis and polyclonal hypergammaglobulinemia. AITL cases have been described with a monoclonal plasma cell population. In some cases, the plasma cell expansion can be so extensive as to partially overshadow or extensively obscure the underlying T-cell neoplasm.[63] In addition, clonal proliferations of B-cells with or without plasma cells mimicking nodal or even extranodal marginal zone lymphoma have been described in the setting of AITL.[64,65]

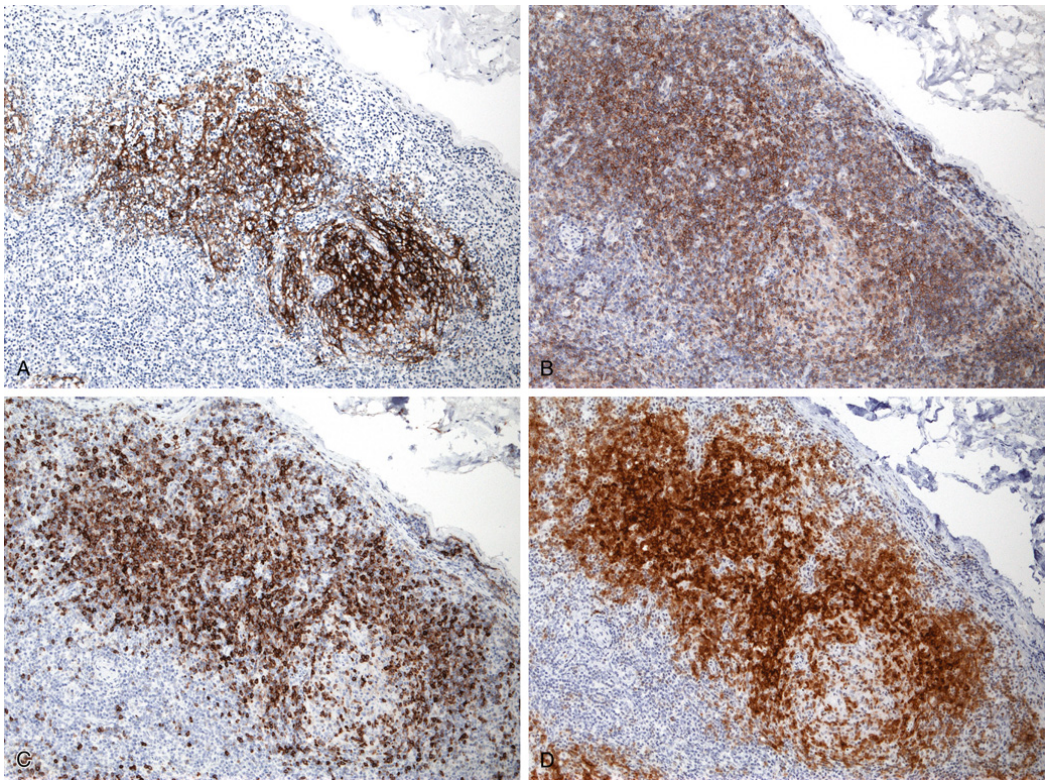

FIGURE 35-9 Follicular helper T-cell lymphoma, angioimmunoblastic type with depleted follicles (pattern 2).A, Expanded CD21-positive follicular dendritic cell (FDC) meshwork extends from the depleted, atrophic follicle. **B,** CD4-positive T cells surrounding the depleted follicle and embedded in the meshwork of CD21-positive FDCs. **C,** The CD4-positive T cells are strongly positive for CD10. Note the absence of CD10 expression in the depleted follicle. **D,** The same cells are PD1 positive.

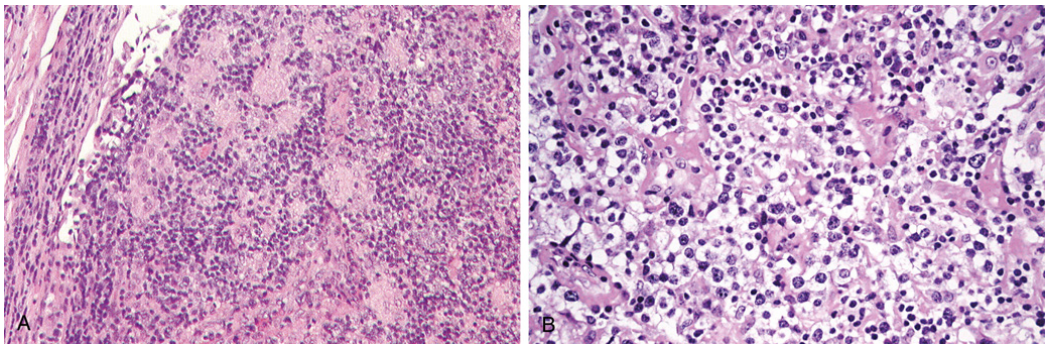

FIGURE 35-10 Pitfalls in the diagnosis of follicular helper T-cell lymphoma, angioimmunoblastic type.A, Follicular helper T-cell lymphoma, angioimmunoblastic type (AITL) with abundant epithelioid histiocytes reaction. Note the open cortical sinus, a characteristic diagnostic feature. **B,** AITL with sheets of large neoplastic T cells.

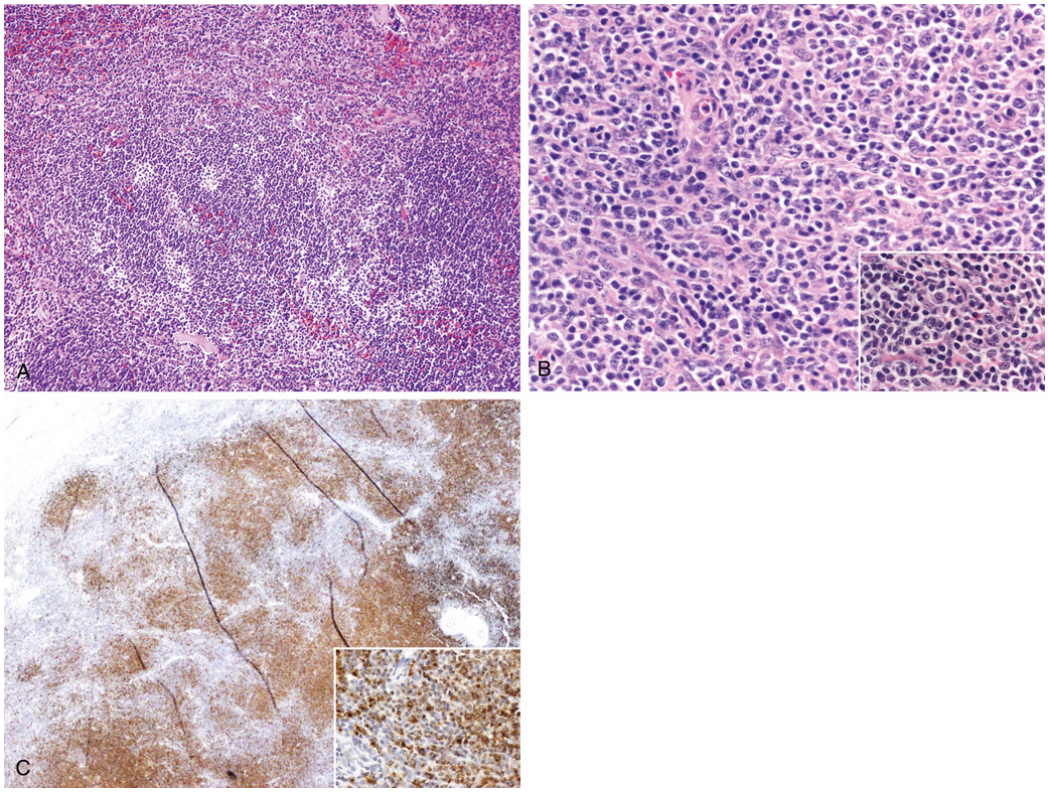

FIGURE 35-11 Follicular helper T-cell lymphoma, follicular type.A, Infiltrate is vaguely nodular with clusters of atypical clear cells. **B,** The lymphoproliferation comprises small-to-medium-sized lymphocytes with pale cytoplasm. **C,** The neoplastic cells express CXCL13, a marker of TFH cells.

Reed-Sternberg–Like Cells

TFH lymphomas may show the presence of typical HRS cells with a classic immunophenotype (CD30 positive, CD15 positive, CD20 positive/negative, EBV positive) (**Fig. 35-13**).[66] Although these HRS-like cells are EBV positive in most cases, rare EBV-negative cases have been described.[61] In contrast to CHL, molecular studies

have revealed clonal rearrangements of TCRG and an oligoclonal pattern of immunoglobulin heavy chain (IGH) gene in the microdissected HRS-like cells. These patients do not seem to be at high risk for progression to CHL.

Immunophenotype

The infiltrating lymphocytes are predominantly T cells (CD3 positive, CD5 positive), usually with an admixture of CD4 and CD8 cells. The neoplastic population in TFH lymphoma is by definition a T cell with a CD4-positive phenotype (**Fig. 35-14A**),[43,67] although CD8-positive T cells may constitute the majority of the lymphoid infiltrate in some cases. In contrast to other types of T-cell lymphoma, loss of pan–T-cell antigen expression is an uncommon finding in AITL. Nevertheless, a recent study showed that loss of CD7 expression seems to be a characteristic finding of TFH lymphomas.[67a] However, loss of surface CD3 is commonly seen by flow cytometry and is a clue to the diagnosis.[68] B cells (CD20 positive, CD79a positive) are found in varying numbers and are occasionally present in follicular aggregates. They are usually small cells but may become larger and activated, especially when infected with EBV. Large atypical cells usually express CD30 and EBV LMP1 can be demonstrated in 30% to 50% of cases, although EBER ISH is more sensitive to the virus.[61]

The proliferation of FDCs, a diagnostic hallmark of AITL, can be readily appreciated with immunohistochemical stains. CD21 or CD23 highlight the disorganized and largely expanded meshworks of FDCs, usually surrounding HEVs in the vast majority of cases (see **Fig. 35-14B**). The exact nature of the CD21-positive cells with dendritic morphology has not been fully resolved. The abnormal proliferation

is centered around the HEVs and is often associated with B-cell follicles in early histologic stages of the disease. It has been postulated that the CD21-positive cells are not true FDCs but activated fibroblastic reticulum cells that have upregulated the CD21 antigen; “pre-FDCs.”[69] Fibroblastic reticulum cells and FDCs are both derived from mesenchymal cell rather than of hematopoietic origin.[70] TFH lymphomas express TFH-associated markers CD10, BCL6, PD1 (CD279), ICOS (CD278), and CXCL13 (**Fig. 35-14A, C–E**), in various numbers and intensities.[6,54,71-73] Overall, PD1 and ICOS are more sensitive than CXCL13, BCL6, or CD10, which in contrast are more specific in identifying the neoplastic TFH cells. By definition, TFH lymphoma derives from a CD4-positive T cell and must express at least two TFH markers.

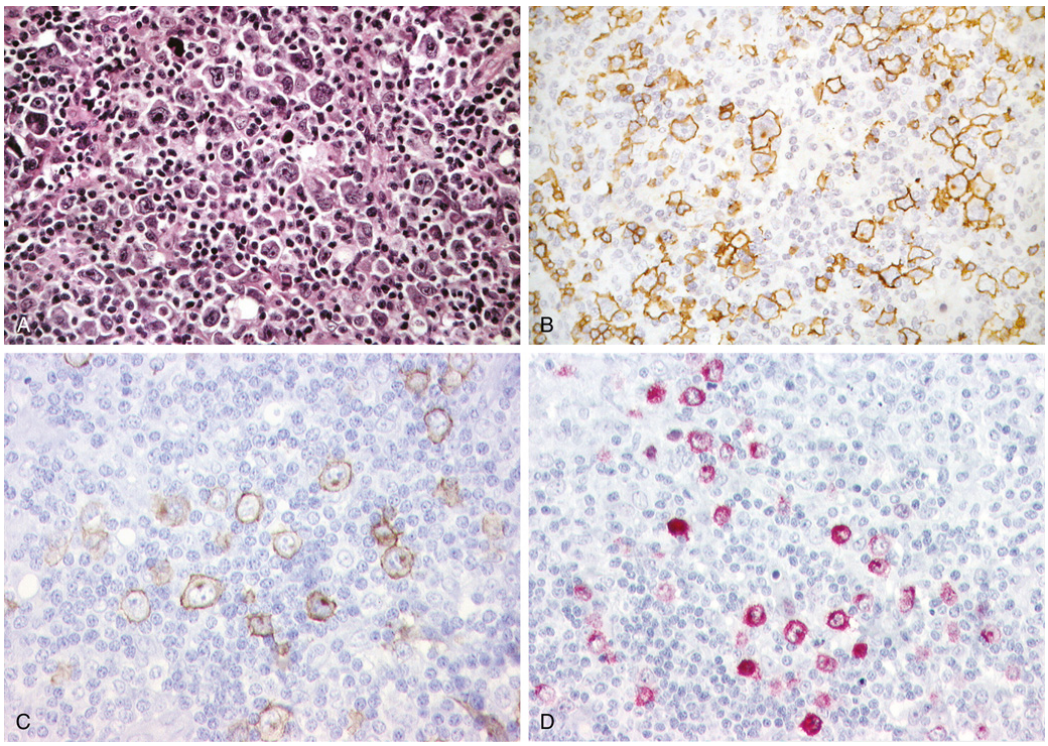

FIGURE 35-12 Follicular helper T-cell lymphoma, angioimmunoblastic type with B-cell lymphoproliferation.A, Proliferation of B-cell blasts in an otherwise typical follicular helper T-cell lymphoma, angioimmunoblastic type (AITL) case. The B cells might resemble centroblasts, immunoblasts, or Hodgkin cells. **B,** CD20 staining highlights the spectrum of B-cell morphology in AITL. **C,** The B cells are positive for CD30. **D,** The B-cell blasts are EBV LMP-1 positive.

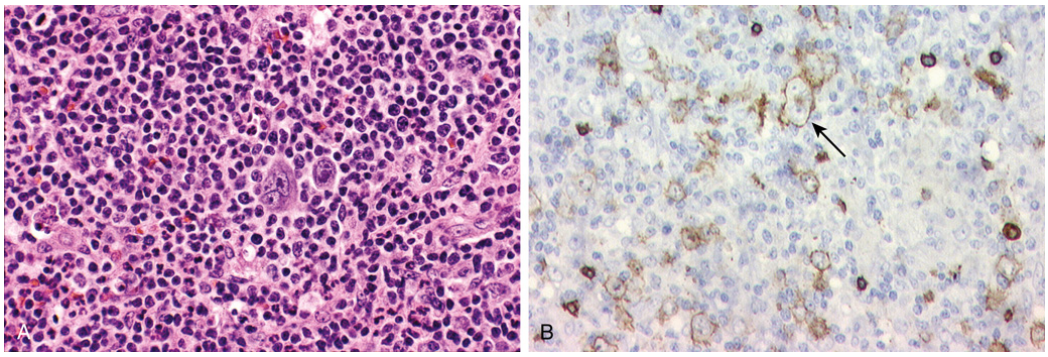

FIGURE 35-13 Follicular helper T-cell lymphoma, angioimmunoblastic type with Reed-Sternberg–like cells.A, Reed-Sternberg (RS)–like cells are depicted. Note the minimal atypia of the surrounding neoplastic T cells. **B,** The RS-like cells are CD20 positive *(arrow)*.

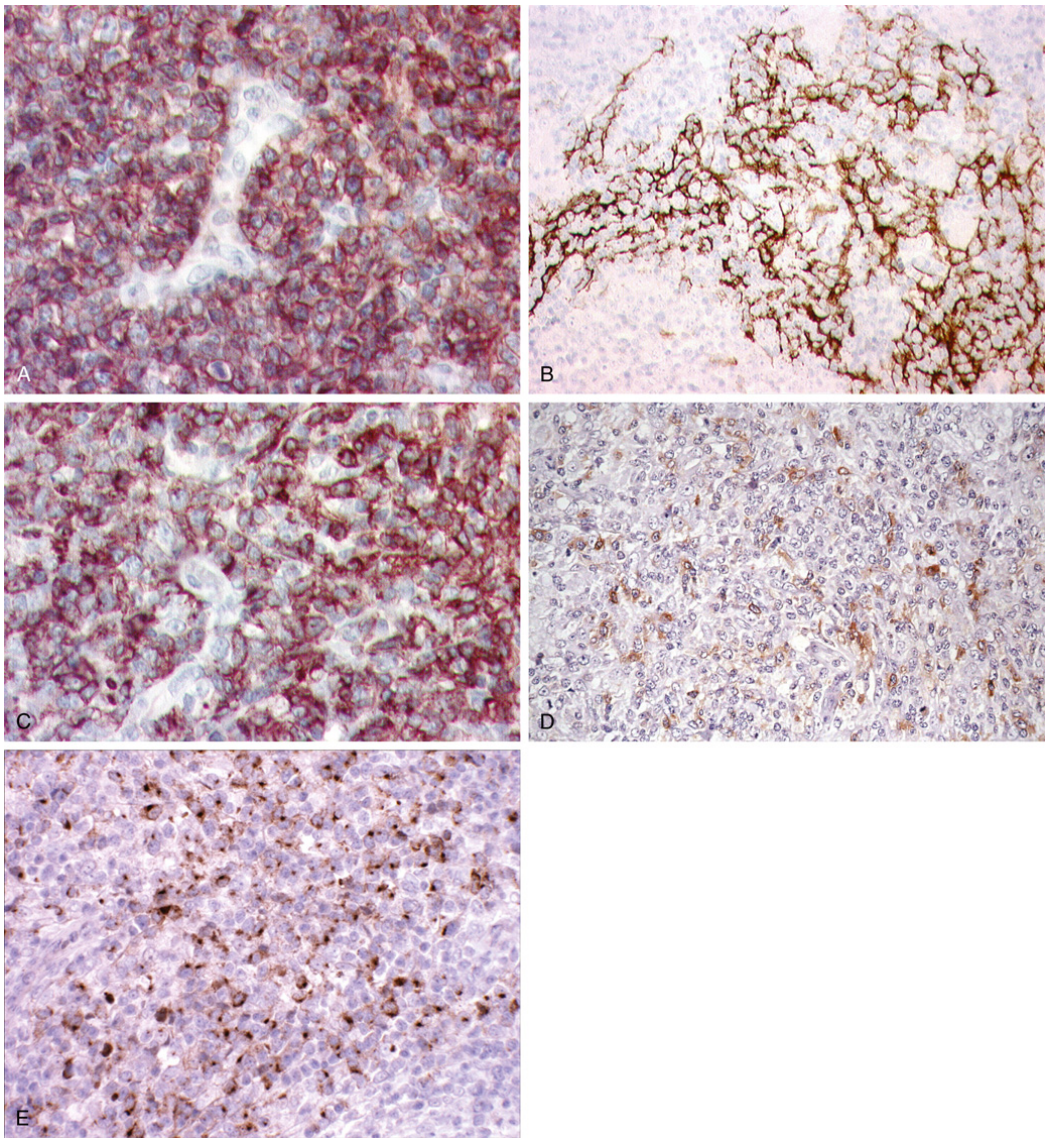

FIGURE 35-14 Characteristic immunophenotype of follicular helper T-cell lymphoma.A, The neoplastic T cells are CD4 positive. **B**, CD21 highlights the marked follicular dendritic cell proliferation, which envelops high endothelial venules. **C,** A case with strong and uniform CD10 expression in the neoplastic cells. **D,** CD10 expression in only a

minority of the tumor cell population. **E,** The neoplastic T cells are strongly CXCL13 positive.

Strong and homogeneous CD10 expression seems to characterize cases with medium-to-large-sized clear cells harboring the *IDH2*^{R172} (NP 002159.2) mutation, which can also be detected by IDH2 immunohistochemistry when involving the specific *IDH2*^{R172K} mutation variant.[74,75] (see **Fig. 35-15A–D**). AITLs with mutations in *RHOA*^{G17V} (NP 001655.1) have been shown to often express several TFH markers and expanded FDC meshworks.[76] Additional markers of normal TFH cells, including CXCR5, CD154, PD1, and SLAM-associated protein (SAP), have been demonstrated by immunohistochemistry to be expressed in the majority of AITL cases.[8] However, no single marker is diagnostic of AITL or TFH derivation.

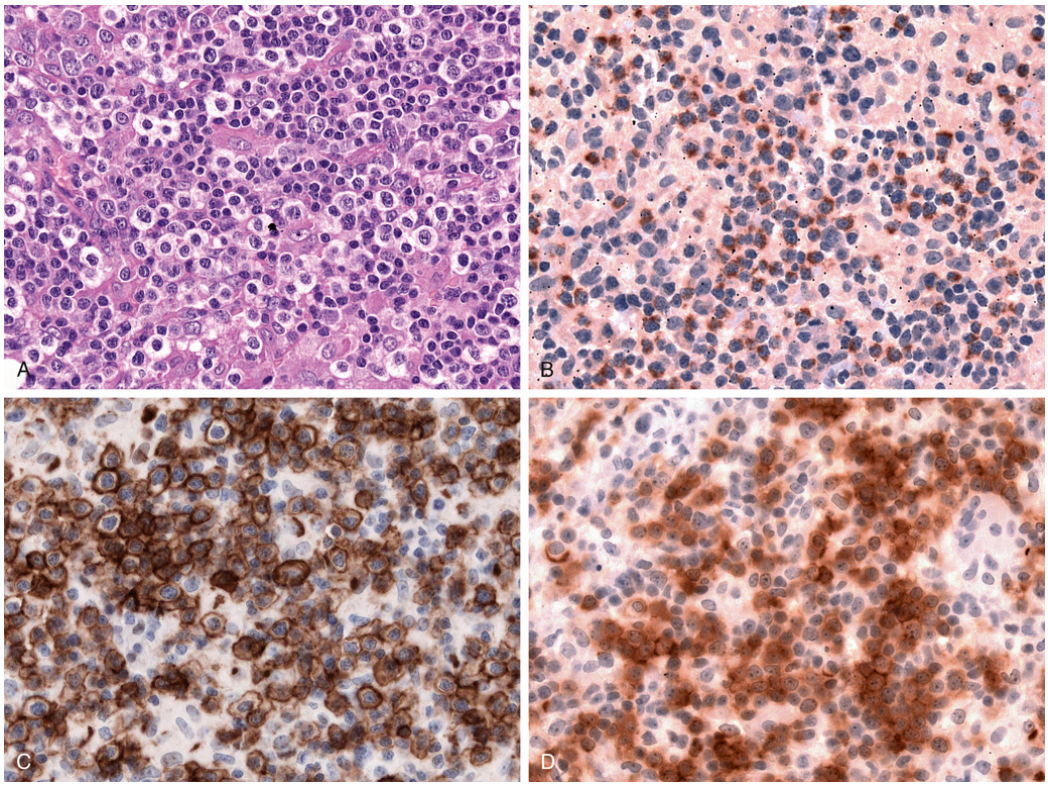

FIGURE 35-15 Follicular helper T-cell lymphoma, angioimmunoblastic-type with *IDH2*^{R172K} mutation.A, Medium-to-large-sized clear cells. Note the tumor cells with abundant clear cytoplasm surrounding high endothelial venules and intermingled with small reactive lymphocytes. **B,** The clear cells are positive for the specific antibody against the *IDH2*^{R172K} mutation. The variant allelic frequency in this case was 17% by next-generation sequencing. The clear cells are strongly positive for ICOS **(C)** and PD1 **(D)**.

Genetics

A monoclonal expansion of T cells with rearranged TR genes is detectable in 75% of AITL.[77] In up to 50% of cases, monoclonal rearrangements of the IGH or light chain (IGL) genes co-exist with rearrangements of TCRB or TCRG, either at presentation or during the course of the disease.[17,78] A small group of cases (7%) with the morphology of AITL reveal clonal rearrangements of the IGH genes alone. Nodal marginal zone lymphoma (NMZL) rich in PD1-positive T cells should be carefully excluded.[79] The presence of IGH rearrangements in bona fide cases of AITL is thought to be caused by a clonal expansion of EBV-infected B cells that are identified in 80% to 90% of lymph nodes involved by AITL.[29] EBV is found mainly in two types of B cells in AITL: cells resembling memory B cells, which show relatively little tendency for clonal expansion, and cells resembling germinal-center B cells, which are driven into massive proliferation and acquire somatic mutations during clonal expansion without selection for a functional B-cell receptor (immunoglobulin-deficient or "forbidden" clones).[80]

Cytogenetic studies have demonstrated trisomy 3, trisomy 5, and an additional X chromosome as the most frequent alterations. By combining classic metaphase cytogenetics and interphase cytogenetics, 89% of AITL cases have been found to harbor aberrant chromosomal clones.[81]

GEP studies showed that AITL is derived from TFH cells, and that genes related to cell morphology, intracellular signaling, and promoting angiogenesis such as VEGF are overexpressed in AITL.[1,82-84] Another interesting finding was that 14% to 20% of so-called "PTCL, NOS" cases expressed the characteristic GEP of AITL, now recognized to be TFH lymphomas, NOS.[1]

A key advance in the understanding of TFH lymphoma pathogenesis was the recognition of common molecular features within this group of lymphomas beyond their similar TFH-like gene expression signatures. Frequent recurrent somatic mutations include genes encoding the epigenetic regulators *TET2* (50%–90%), *DNMT3A* (30%–40%), and *IDH2*^{R172} (20%–45%), the small GTPase, *RHOA*^{G17V} (50%–70%) and components of the TCR signaling pathways such as *PLCG1* (14%), *CD28* (9%–11%), *VAV1* (5%), and *FYN* (3%–4%).[11,85-89] Mutations in *RHOA*^{G17V} have been identified in up to 70% of AITL,[11,12,87] in follicular type,[13,41] and TFH lymphoma, NOS (60%), and are considered a hallmark of TFH lymphomas.[11,12,87,89,90] The main function of RHOA is to promote motility and adhesion, and in T cells, RHOA is required for the regulation of transendothelial migration.[91] The mutation enables RHOA to interact with VAV1, a downstream molecule of the TR,[92] and enhances signal transduction by the TR.[93-95] Mutations in *IDH2*^{R172} (NP_002159.2) occur almost exclusively in AITL, usually with concurrent *TET2* and *RHOA*^{G17V} mutations. This mutation confers increased genome-wide promoter hypermethylation and is associated with characteristic morphologic features including medium-to-large-sized clear tumor cells with strong TFH phenotype.[74,83,88] Recurrent oncogenic fusion genes have been reported, including *ICOS*::*CD28, ITK*::*SYK,* and *VAV1* fusions.[96] Most of these genomic alterations are seen across the spectrum of TFH lymphomas with the exception of *IDH2*^{R172} mutations, which are characteristic of AITL and *ITK*::*SYK* fusions, which are mostly associated with TFH lymphoma, follicular type.[97]

Loss-of-function mutations in the methylation associated genes *TET2* and *DNMT3A* are likely to occur in a background of clonal hematopoiesis (CH), providing survival advantage to TFH cells.[18,86,98,99] These mutations are not restricted to T cells and have been demonstrated in B cells and hematopoietic stem cells, whereas $RHOA^{G17V}$ and $IDH2^{R172}$ mutations appear to be confined to the neoplastic T cells. A scenario of multistep and multilineage tumorigenesis has been suggested, in which the initial mutations in *TET2* or *DNMT3* occur in a hematopoietic stem cell with subsequent acquisition of *RHOA, IDH2,* and TCR gene mutations important for T-cell function, leading to TFH lymphoma.[100] CH is also associated with myeloid neoplasms.[101] This explains the frequent association of AITL with myeloid neoplasms, mainly chronic myelomonocytic leukemia, acute myeloid leukemia, and myelodysplastic syndrome, in the same patients. In some patients, it has been demonstrated that the myeloid neoplasm and AITL share common ancestral mutations in *TET2* and *DNMT3A,* suggesting that they arise from divergent evolution of a common CH clone.[18,99] More recently has been shown an increased association of TFH and cytotoxic T-cell lymphomas sharing TET2 and/or DNMT3A mutations suggesting that cytotoxic T-cell lymphomas also develop in a background of CH.[101a]

Clinical Course and Prognosis

The clinical course of AITL, which is the prototype of TFH lymphomas, is characterized by rapid progression in most patients; however, spontaneous remissions may occur.[36] The median survival is less than 3 years.[102,103] The majority of deaths are caused by infectious complications rather than progressive lymphoma, which

makes AITL particularly difficult to treat with chemotherapy. Owing to the underlying immunodeficiency and abnormalities of T-cell function, in addition to the infectious complications, patients may have expanding EBV-positive B-cell clones that may lead to EBV-positive large B-cell lymphomas in rare cases.[29,62] The clinical course appears to correlate with the extent of systemic symptoms at presentation (i.e., rash, pruritus, edema, ascites). Because 90% of AITL patients have stage III or IV disease at presentation, staging is not very useful in predicting clinical outcome for most patients. Male gender and the presence of mutations in *TET2, DNMT3A,* and *IDH2* have been associated with inferior prognosis.[37,103,104] A prognostic index developed for TFH lymphoma patients has been shown to be more useful than the IPI.[36] A new predictive score that has been developed categorizes patients into three prognostic groups based on beta-2-microglobulin and C-reactive protein levels, age, and ECOG (Eastern Cooperative Oncology group) performance status.[102] The clinical course and the prognosis of TFH lymphomas, follicular type and NOS, is uncertain but may not entirely differ from that of AITL.[6,13,16,27,103,105,106] Two studies have described an overall survival of 50% to 60% for TFH lymphoma, follicular type at 2 years.[16,26] Recent studies suggest that TFH lymphomas respond better to histone deacetylase and DNA methyltransferase inhibitors because of the common alterations in epigenetic modifying genes identified in this disease.[39,40,107]

Differential Diagnosis

Although the histopathologic features of AITL are well described, there is considerable morphologic overlap with a variety of benign

and malignant lymphoid proliferations, including T-zone hyperplasia (paracortical hyperplasia), CHL, and PTCL, NOS (**Table 35-2**). T-zone hyperplasia is usually associated with viral infections or with a hyperimmune reaction secondary to an autoimmune disease. An important hint to the diagnosis of T-zone or paracortical hyperplasia is preservation of the lymph node architecture, with the presence of follicles and germinal centers and the lack of aberrant FDC proliferation. The paracortical area is expanded with a mixed infiltrate of medium-sized and small-sized lymphoid cells without atypia. Frequently, the numerous plasma cells, immunoblasts, and activated lymphocytes may mimic the cellular composition of AITL. Immunophenotypical analysis reveals a mixed CD4-CD8 population with scattered CD20-positive cells and variable numbers of CD25-positive and CD30-positive cells. No TCR rearrangements are identified. Moreover, CD10-positive cells, if present, are confined to the follicles.

The differential diagnosis between especially tumor-cell–rich variants of AITL and TFH lymphoma, NOS, can be challenging; however, currently there is no effect on clinical management. Morphologic features that favor the diagnosis of AITL are open, usually distended peripheral cortical sinuses; proliferation of FDCs highlighted by CD21/CD23; and prominent arborizing HEVs.[5,54,64,73,108] Occasionally the presence of numerous EBV-positive B cells, some of which acquire HRS-like features, may obscure the underlying TFH lymphoma or mimic CHL.[61,62,66] These cells have the immunophenotype of HRS cells (CD15 positive, CD30 positive, CD20 positive) and harbor EBV in most cases (EBER and LMP-1). Because many AITL cases show minimal cytologic atypia of

T cells, the distinction from CHL may be difficult. In contrast to CHL, molecular studies reveal clonal rearrangements of the TCRγ chain gene in TFH lymphomas. Finally, because of the frequent occurrence of randomly scattered B blasts in TFH lymphomas, especially AITL, variant patterns of nodular lymphocyte predominant B-cell (Hodgkin) lymphoma (NLPBL/NLPHL) and T-cell/histiocyte–rich large B-cell lymphoma (THRLBCL) should be included in the differential diagnosis. In NLPBL and THRLBCL, the background infiltrate is not as polymorphic as in TFH lymphomas and the B blasts are generally CD30 negative and EBV negative. However, in NLPBL, expanded meshworks of FDCs may occur. Molecular analysis may show monoclonal IGH gene rearrangements, and, especially, no TCR gene rearrangements are identified. A recently described pitfall in the differential diagnosis of AITL are cases of NMZL rich in PD1-positive T cells.[79] In these cases, demonstration of IG clonality and lack of typical mutations characteristic of TFH lymphomas support the diagnosis of NMZL.[109]

Table 35-2

+, Nearly always positive; −/+, may be positive, but usually negative; +/−, may be negative, but usually positive; *AITL,* angioimmunoblastic T-cell lymphoma; *EBV,* Epstein-Barr virus; *FDC,* follicular dendritic cell; *HEV,* high endothelial venule; *HRS,* Hodgkin–Reed-Sternberg; *IG,* immunoglobulin genes; *LMP-1,* latent membrane protein-1; *PTCL, NOS,* peripheral T-cell lymphoma, not otherwise specified; *TR,* T-cell receptor.

Pearls and Pitfalls

- The different morphologic subtypes of follicular helper T-cell (TFH) lymphomas have distinctive histologic features, but these features may overlap and the different subtypes may show considerable plasticity within the same patient at diagnosis and between diagnostic samples and relapses.
- Angioimmunoblastic T-cell lymphoma (AITL) is the prototypic form of TFH lymphoma, whereas TFH lymphoma, follicular type and NOS are much rarer.
- The clinical presentation of AITL is an essential diagnostic feature—localized lymphadenopathy is rare.
- B-cell or plasma-cell proliferation, EBV positive or EBV negative, is virtually always present in affected lymph nodes.
- In early phases, reactive follicular hyperplasia may be present, mimicking a reactive process.
- Highly characteristic histologic features of AITL include the following:
    - Extension of the infiltrate beyond the lymph node capsule into the perinodal fat, frequently sparing the preserved cortical sinuses, which are dilated
    - Prominent arborizing postcapillary high endothelial venules
- The most helpful routine immunophenotypical tools for diagnosis are demonstration of expanded FDCs meshworks in AITL with CD21 or CD23 and expression of TFH markers CD10, BCL6, CXCR3, PD1, and ICOS (CD278) in T cells in all forms of TFH lymphomas.

- In “early” pattern 1, the atypical mislocalization of CD10-positive, PD1-positive cells, sometimes with abundant clear cytoplasm surrounding the reactive germinal centers, is a clue to the diagnosis.
- EBV-positive B cells are nearly always present and may evolve to EBV-positive large B-cell lymphoma or a mimic of classic Hodgkin lymphoma.
- Nodal marginal zone lymphoma rich in PD1-positive T-cells might mimic the diagnosis of AITL.

ALK- Negative Anaplastic Large Cell Lymphomas Associated With Breast Implants

Definition and Background

Among the heterogeneous group of hematopoietic neoplasms with a predominant population of large cells, Stein and coworkers[1] recognized a subgroup of tumors with large cells exhibiting bizarre morphologic features and prominent sinusoidal invasion and expressing the Ki-1 antigen (now referred to as CD30). Based on the strong expression of this molecule, these tumors were designated *Ki-1 lymphoma*.[1] Because of the lack of strict morphologic criteria, some

tumors were diagnosed as Ki-1 lymphoma simply because they consisted of large cells positive for the CD30 antigen, whatever their B-, T-, or null-cell phenotype. Later, the term *Ki-1 lymphoma* was replaced by anaplastic large cell lymphoma (ALCL). Although there was no clear consensus among pathologists with regard to the definition of *anaplastic,* and despite the fact that some of these tumors consist of small-to-medium-sized cells, the term *ALCL* was incorporated into most classifications. Later, it was discovered that a significant proportion of ALCLs are associated with the t(2;5)(p23;q35) translocation.[2] A major advance was made with the cloning of this translocation[3] and the production of antibodies detecting its gene product—fusion of anaplastic lymphoma kinase (ALK).[4] As a consequence, ALCLs were divided in two main categories—those positive for ALK protein and those lacking this marker. In the World Health Organization (WHO) 3rd ed. classification of hematopoietic neoplasms, ALK-positive and ALK-negative ALCLs were considered a single disease entity and were defined as lymphomas consisting of lymphoid cells that are usually large and have abundant cytoplasm and pleomorphic, often horseshoe-shaped nuclei.[5] The cells are CD30 positive, and most cases express cytotoxic granule-associated proteins[6,7] and epithelial membrane antigen (EMA).[8] It became clear that although ALCLs expressing ALK are relatively homogeneous, cases with similar morphology and phenotype but lacking ALK expression are much more heterogeneous. ALCLs lacking ALK also differ from peripheral T-cell lymphomas, not otherwise specified (PTCL, NOS), some of which can be positive for CD30 in a variable number of cells. Current thinking recognizes ALCL, ALK positive, and ALCL, ALK negative as distinct diseases. Breast-implant–associated ALCL, also ALK-negative, is a recently recognized distinct entity and

will be discussed. Systemic ALCL, both ALK positive and ALK negative, must be distinguished from primary cutaneous ALCL and from other subtypes of T-cell or B-cell lymphoma with anaplastic features or CD30 expression.[9]

Anaplastic Large Cell Lymphoma, Alk Positive

Synonyms and Related Terms

WHO revised 4th ed.: Anaplastic large cell lymphoma, ALK-positive

WHO proposed 5th ed.: ALK-positive anaplastic large cell lymphoma

Epidemiology

ALCL accounts for 5% of all non-Hodgkin lymphomas and 10% to 30% of childhood lymphomas.[10] ALK-positive ALCL is most frequent in the first 3 decades of life and shows a slight male predominance.[11,12]

Etiology

No pathogenic factor has been demonstrated. However, in rare cases, an association with recent insect bites has been suggested.[13,14] Occasional cases occur in human immunodeficiency virus (HIV)–positive patients or after solid organ transplantation.[15] It is unlikely that these conditions play a primary etiologic role, but emergence of the disease may be facilitated by abnormal cytokine production.

Clinical Features

Most patients (70%) with ALK-positive ALCL present with advanced stage III to IV disease with peripheral or abdominal lymphadenopathy, often associated with extranodal infiltrates and involvement of the bone marrow.[10,12] Patients often show B symptoms (75%), especially high fever.[10,12,16] Several cases with a leukemic presentation have been reported.[17-19]

Primary systemic ALCL positive for the ALK protein frequently involves both lymph nodes and extranodal sites. Extranodal sites commonly include skin (26%), bone (14%), soft tissues (15%), lung (11%), and liver (8%).[10,12,16] Retinal infiltration responsible for blindness and placental involvement have also been reported.[20] Involvement of the gut and central nervous system is rare. However, occasional cases of ALK-positive ALCL in the stomach, bladder, or central nervous system have been observed (authors' unpublished observations).[21,22] Mediastinal disease is less frequent than in Hodgkin lymphoma. The incidence of bone marrow involvement is approximately 10% when analyzed with hematoxylin and eosin (H&E) but increases significantly (30%) when immunohistochemical stains for CD30, EMA, or ALK are used (**Fig. 36-1**).[23] This is because bone marrow involvement is often subtle, with only scattered malignant cells that are difficult to detect by routine examination. Most patients have circulating antibodies against nucleophosmin (NPM)-ALK protein, and these antibodies may persist in patients who are apparently in complete remission.[24]

Morphology

The spectrum of morphologic features of ALK-positive ALCL is wider than was initially described,[1,11,25-29] ranging from small cell neoplasms, which pathologists might mistake for PTCL, NOS, to

tumors in which very large cells predominate.[11] However, all cases contain a variable proportion of large cells with eccentric horseshoe-shaped or kidney-shaped nuclei, often with an eosinophilic region near the nucleus. These cells have been referred to as *hallmark cells* (**Fig. 36-2A**) because they are present in all morphologic patterns.[11] Although hallmark cells are typically large, smaller cells with similar cytologic features may be seen and can greatly aid in making the diagnosis.[11] Depending on the plane of the section, some cells may appear to contain cytoplasmic inclusions. These are not true inclusions, however, but invaginations of the nuclear membrane. Cells with these features have been referred to as *donut cells* (see **Fig. 36-2A**).[30,31] In some cases, the nuclei are round to oval, and the proliferation appears quite monomorphic (see **Fig. 36-7A**).

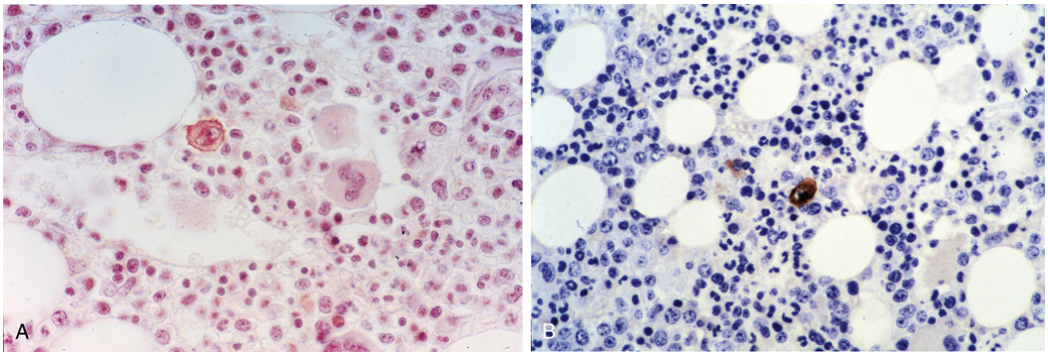

FIGURE 36-1 Although the bone marrow biopsy was considered to be uninvolved on standard histopathologic examination, immunohistochemistry shows scattered malignant cells strongly positive for CD30/Ber-H2 **(A)** and ALK1 antibody **(B)**.

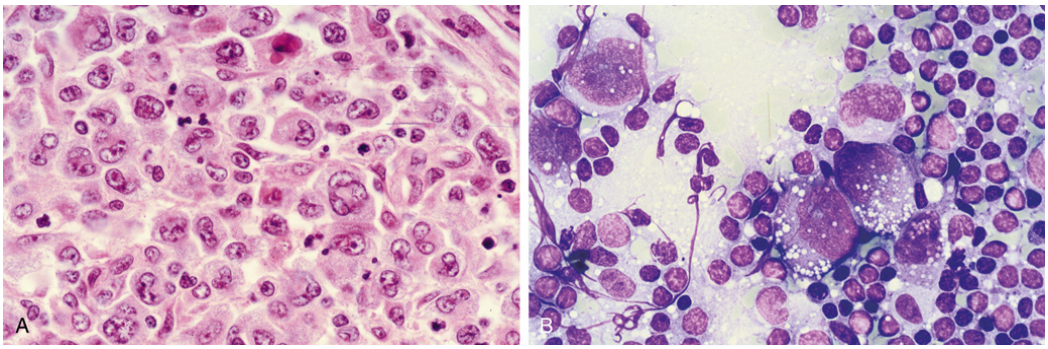

FIGURE 36-2 Anaplastic large cell lymphoma, common pattern.A, Predominant population of large cells with irregular nuclei. Note the large "hallmark" cells with eccentric kidney-shaped nuclei. One "donut" cell can be seen in this field. **B,** Lymph node imprint preparation shows lymphoma cells with vacuolated cytoplasm.

The tumor cells have more abundant cytoplasm than most other lymphomas. The cytoplasm may appear clear, basophilic, or eosinophilic. On lymph node imprints these cells show vacuolated cytoplasm (see **Fig. 36-2B**). Multiple nuclei may occur in a wreathlike pattern, giving rise to cells resembling Reed-Sternberg (RS) cells. The nuclear chromatin is usually finely clumped or dispersed, with multiple small basophilic nucleoli. Prominent inclusion-like nucleoli are relatively uncommon, aiding in the differential diagnosis with classic Hodgkin lymphoma (CHL).[32]

ALCLs exhibit a very broad range of cytologic appearances.[11,32,33] Five morphologic patterns have been recognized since the WHO 4th ed.[34]

Anaplastic Large Cell Lymphoma, Common Pattern

ALCL, common pattern (70%) is composed predominantly of pleomorphic large cells with the hallmark features described earlier. Tumor cells with more monomorphic, rounded nuclei also occur, either as the predominant population or mixed with the more pleomorphic cells. Rarely, erythrophagocytosis by malignant cells may be seen. When the lymph node architecture is only partially effaced, the tumor characteristically grows within the sinuses and thus may resemble a metastatic tumor (**Fig. 36-3**). Tumor cells may also colonize the paracortex and often grow in a cohesive manner (**Fig. 36-4**).

Anaplastic Large Cell Lymphoma, Lymphohistiocytic Pattern

ALCL, lymphohistiocytic pattern (10%) is characterized by tumor cells admixed with a large number of histiocytes (**Fig. 36-5A–C**).[11,27,35,36] The histiocytes may mask the malignant cells, which are often smaller than in the common pattern (see **Fig. 36-5D**). The neoplastic cells often cluster around blood vessels and can be highlighted by immunostaining using antibodies to CD30 (see **Fig. 36-5E–F**), ALK, or cytotoxic molecules. Occasionally the histiocytes show signs of erythrophagocytosis. The histiocytes typically have finely granular eosinophilic cytoplasm and small, round uniform nuclei. Well-formed granulomas are absent, and clusters of epithelioid cells (as may be seen in the lymphoepithelioid cell variant of PTCL, NOS) are not seen.

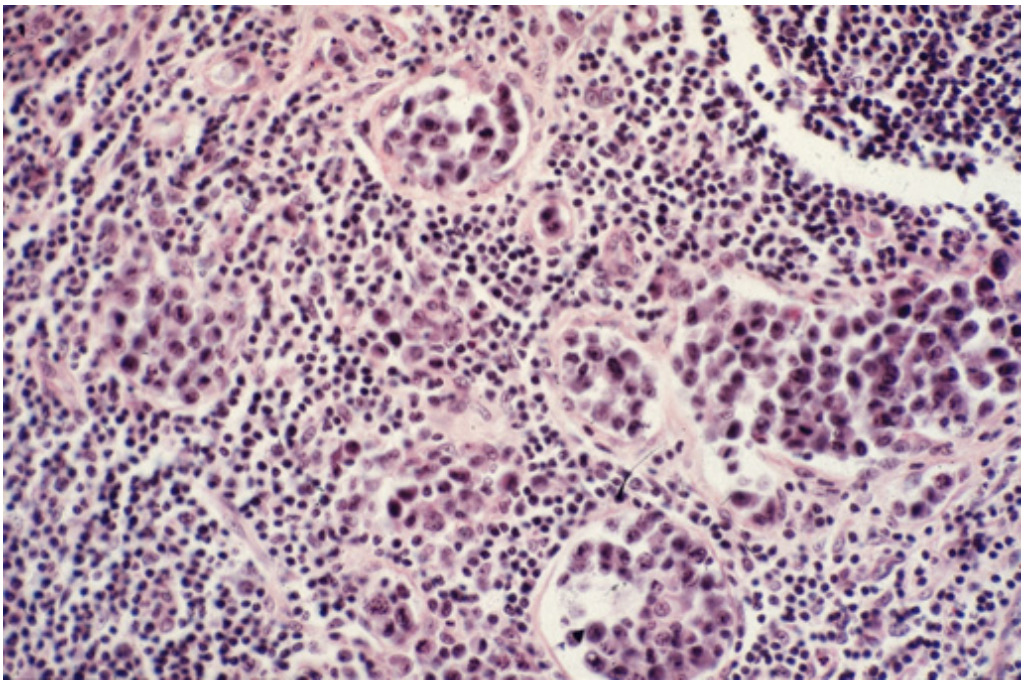

FIGURE 36-3 General features of anaplastic large cell lymphoma, common pattern. In some cases the predominant sinusoidal growth pattern mimics a metastatic malignancy.

Anaplastic Large Cell Lymphoma, Small Cell Pattern

ALCL, small cell pattern (10%) shows a predominant population of small-to-medium-sized neoplastic cells with irregular nuclei (**Fig. 36-6A–C**).[11,26,30] However, morphologic features vary from case to case, and cells with round nuclei and clear cytoplasm ("fried egg" cells) may predominate. Hallmark cells are always present and are often concentrated around blood vessels (see **Fig. 36-6D**).[11] Usually there is massive infiltration of the perinodal connective tissue. This morphologic variant of ALCL is often misdiagnosed as PTCL, NOS by conventional examination. When the blood is involved, atypical cells reminiscent of flower-like cells may be observed in smear

preparations.[17,18] It is likely that the small cell and lymphohistiocytic patterns are closely related.[9,31]

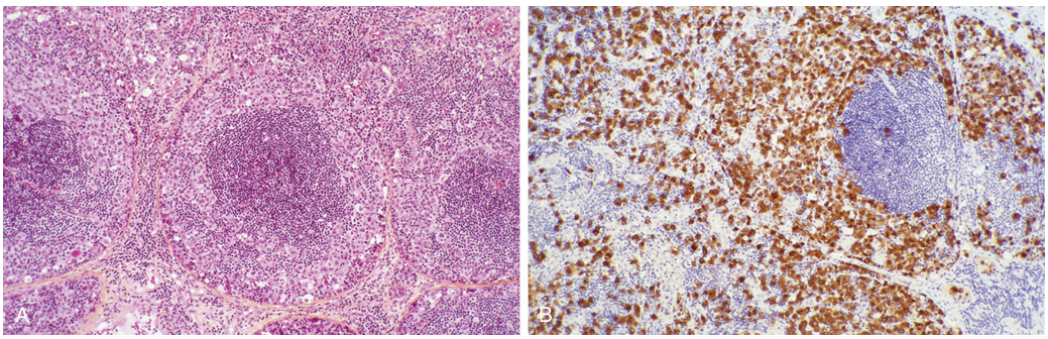

FIGURE 36-4 Anaplastic large cell lymphoma, common pattern.A, Classic case with a predominant perifollicular and paracortical pattern on hematoxylin and eosin (H&E) stain. **B,** ALK1 staining.

Anaplastic Large Cell Lymphoma, Hodgkin-Like Pattern

ALCL, Hodgkin-like pattern (1%–3%) is characterized by morphologic features mimicking nodular sclerosis CHL.[37] These cases show a vaguely nodular fibrosis associated with capsular thickening and a significant number of tumor cells resembling classic RS cells associated with hallmark cells (see **Fig. 36-7E**). In the past, many tumors with similar features were referred to as *Hodgkin-like ALCL*. However, most cases designated as such were negative for ALK and were more likely variants of CHL rich in Hodgkin cells or lymphomas with features intermediate between CHL and diffuse large B-cell lymphoma—so-called *gray zone lymphomas*.[31,38] It must be stressed that CD30-positive lymphomas, with or without a sinusoidal growth pattern, should not be diagnosed as ALCL,

Hodgkin-like unless they are positive for ALK. In cases negative for ALK protein, additional immunophenotypic and molecular studies usually permit their classification as aggressive B-cell or T-cell lymphomas.

Anaplastic Large Cell Lymphoma, Composite Pattern

ALCL with a composite pattern accounts for 10% to 20% of cases. These cases have features of more than one pattern in a single lymph node biopsy. In addition, in some cases, a repeat biopsy taken at the time of relapse may reveal morphologic features that differ from those seen initially, suggesting that the morphologic patterns of ALCL are simply variations of the same entity.[11,26]

Other Histologic Patterns

Other histologic patterns may be seen, although they are not recognized as distinctive patterns in the WHO classification. They are often responsible for diagnostic difficulties. These include a giant cell–rich pattern (**Fig. 36-7B**), a sarcomatoid pattern (see **Fig. 36-7C**), and a "signet ring"–like pattern (see **Fig. 36-7D**). Some ALCLs may mimic a metastatic malignancy, with cohesive neoplastic cells encased within a dense fibrosis (see **Fig. 36-7F**). Some ALCLs may show a striking edematous or myxoid background, either focally or throughout the whole tissue section (see **Fig. 36-7G**). Tumors with such morphology have been reported as hypocellular ALCL.[39] A starry-sky appearance may also be observed, suggesting Burkitt lymphoma on low-power magnification.

Immunophenotype

By definition, all ALCLs are positive for CD30. In most cases, virtually all neoplastic cells show strong CD30 staining on the cell membrane and in the Golgi region (**Fig. 36-8A**). In the small cell variant and sometimes in the lymphohistiocytic variant, the strongest immunostaining is seen in the large cells, which often cluster around blood vessels (see Figs. **36-5F** and **36-6D**)[11]; smaller tumor cells may be only weakly positive or even negative for CD30. The majority of ALCLs are positive for EMA.[8,11] The staining pattern for EMA is usually like that seen with CD30, although in some cases only a proportion of malignant cells is positive (see **Fig. 36-8B**).

Most ALCLs express one or more T-cell or natural killer (NK)-cell antigens.[10,11,40] However, owing to the loss of several pan–T-cell antigens, some cases may have an apparent null-cell phenotype. Because no other distinctions can be found in ALK-positive ALCLs with a T-cell versus null-cell phenotype, they are considered part of the same entity.[11,41] CD3, the most widely used pan–T-cell marker, is negative in more than 75% of cases.[11] This tendency for loss of CD3 is also seen in ALK-negative ALCL. CD5 and CD7 are often negative as well. CD2 and CD4 are more useful and are positive in a significant proportion of cases. CD43 is expressed in more than two-thirds of cases but lacks lineage specificity (see **Fig. 36-8C**). Most cases exhibit positivity for the cytotoxic-associated antigens TIA-1, granzyme B, and perforin (see **Fig. 36-8D–E**).[6,7] CD8 is usually negative, but rare CD8-positive cases exist. Occasional cases are positive for CD68/KP1 but not CD68/PGM1.

Tumor cells are variably positive for CD45 and CD45RO but strongly positive for CD25.[8] Blood group antigens H and Y (detected with antibody BNH.9) have been reported in more than 50% of cases (see **Fig. 36-8F**).[42] CD15 expression is occasionally observed.[11]

ALCLs are consistently negative for Epstein-Barr virus (EBV) (i.e., EBV-encoded small RNA [EBER] and latent membrane protein-1 [LMP-1]).[43] A study employing array technology to detect new genes expressed in ALCL found that clusterin is aberrantly expressed in all cases of systemic ALCL but not in primary cutaneous ALCL.[44] Most ALK-positive ALCLs are negative for BCL2 (see **Fig. 36-8G**).[45] A number of other antigens are expressed in ALCL, but they are not of diagnostic value. They include CD56[46-48]; SHP1 phosphatase[49]; BCL6, C/EBPβ, and serpinA1[50,51]; myeloid-associated antigens CD13 and CD33[52]; and p63.[53] Tumor cells express PDL1 via induced expression of STAT3 activity by NPM-ALK, providing rationale for immune checkpoint inhibitors.[54]

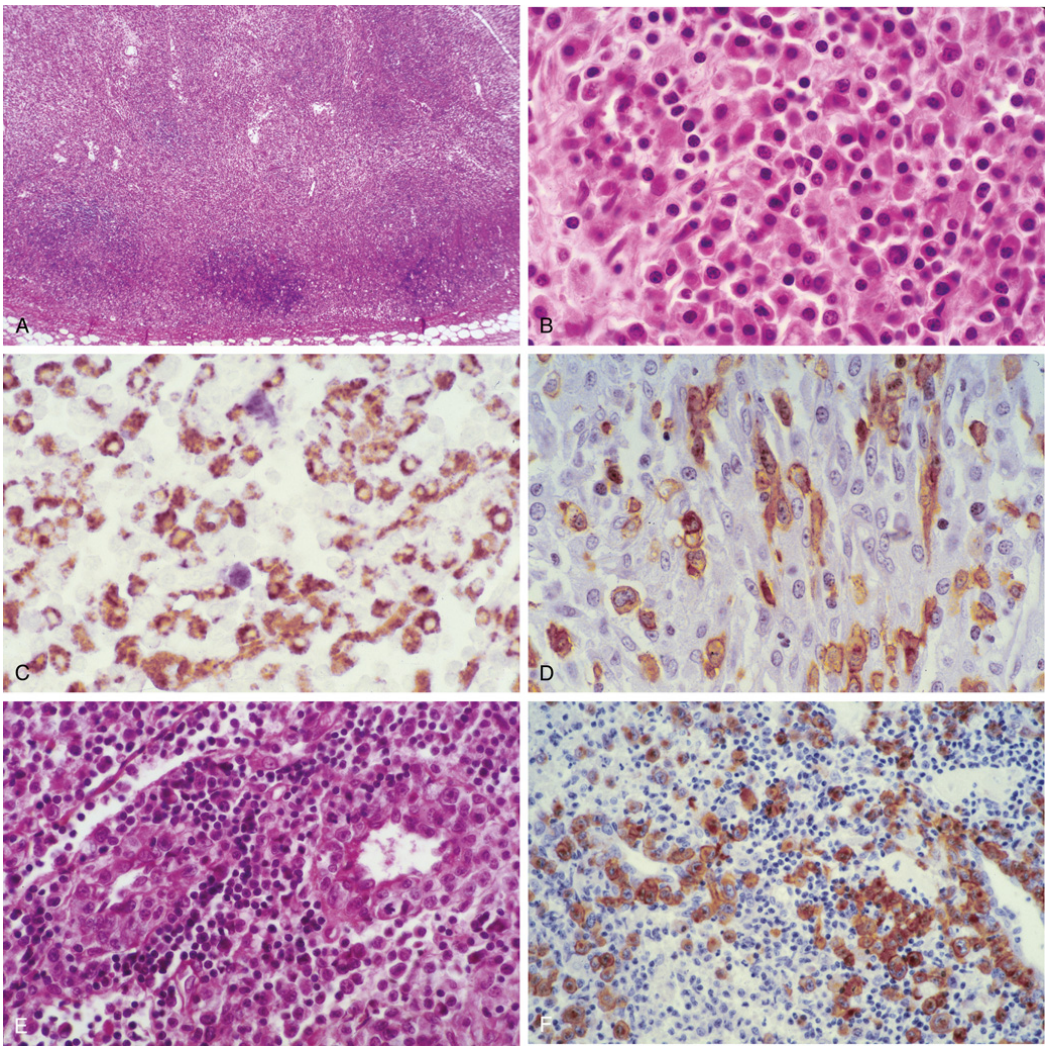

FIGURE 36-5 Anaplastic large cell lymphoma, lymphohistiocytic pattern.A, At low power, the infiltrate is mainly paracortical in distribution. **B,** On a high-power view, malignant cells are admixed with a predominant population of non-neoplastic histiocytes. The malignant cells may be extremely rare and difficult to detect on hematoxylin and eosin (H&E) stain. **C,** Double immunostaining with CD68/KP1 *(brown)* and ALK1 *(blue)* confirms the paucity of malignant cells (blue nuclear staining). **D,** CD30 staining

shows that the malignant cells vary in size, with some exhibiting a fibroblast-like morphology. **E** and **F,** Characteristically, the neoplastic cells often cluster around blood vessels and can be highlighted by immunostaining using antibodies to CD30. Such a perivascular pattern is also observed in anaplastic large cell lymphoma, small cell variant.

The ALK staining may be cytoplasmic, nuclear, and nucleolar or it may be restricted to either the cytoplasm or, more rarely, the cell membrane (**Fig. 36-9**). Among hematopoietic neoplasms, ALK expression is virtually specific for ALCL because it is absent from all normal postnatal human tissues except for rare cells in the brain[55] and absent from hematopoietic neoplasms other than ALCL, with the exception of ALK-positive large B-cell lymphomas (see **Fig. 36-13**)[56] and a novel form of ALK-positive histiocytosis seen in infancy.[57] It is important to note that in the small cell pattern and, to a lesser extent, in the lymphohistiocytic pattern, ALK staining may be restricted to scattered large cells. However, ALK staining performed without a nuclear counterstain often reveals small cells showing restricted nuclear staining.

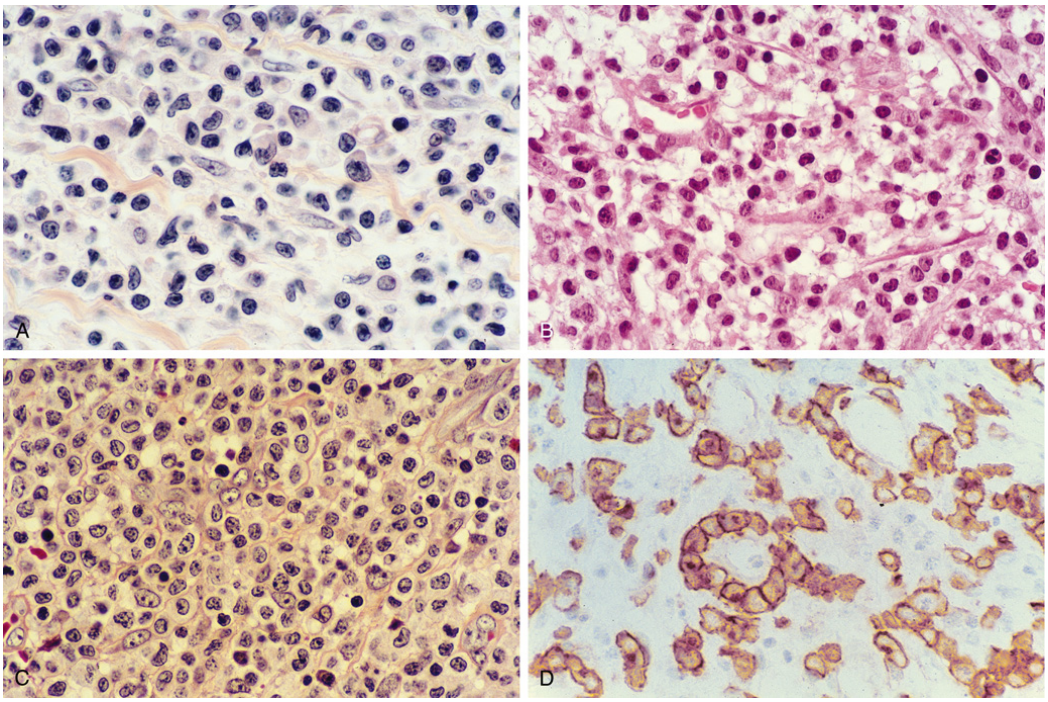

FIGURE 36-6 Anaplastic large cell lymphoma, small cell variant.A–B, Predominant population of small cells with irregular nuclei associated with scattered hallmark cells with kidney-shaped nuclei. **C,** This case exhibits a monomorphic population of small cells with clear cytoplasm ("fried egg" cells). **D,** In most cases the neoplastic cells are perivascular, a pattern that is highlighted by CD30 staining. Note that the large cells are strongly positive for CD30, whereas the small-sized and medium-sized malignant cells are only weakly stained.

Genetics and Molecular Findings

Approximately 90% of ALCLs show clonal rearrangement of the T-cell receptor (TR) genes, irrespective of whether they express T-cell

antigens.[6] The majority of ALCLs are associated with a reciprocal translocation, t(2;5)(p23;q35), which juxtaposes the gene at 5q35 encoding NPM, a nucleolar-associated phosphoprotein, with the gene at 2p23 coding for ALK, a receptor tyrosine kinase.[3,58] Polyclonal and monoclonal antibodies recognizing the intracellular portion of ALK react with both NPM-ALK protein and the full-length ALK protein, but no normal lymphoid cells express full-length ALK; as a consequence, immunostaining with anti-ALK has been used to detect ALCL cases carrying the t(2;5) translocation.[3,55,59] However, variant translocations involving *ALK* and other partner genes on chromosomes 1, 2, 3, 4, 8, 9, 11, 17, 19, and 22 also occur (**Table 36-1**).[60-70] All result in the upregulation of *ALK*, but the distribution of the staining varies, depending on the translocation. The classic t(2;5) translocation leads to positive staining for ALK in the nucleolus, nucleus, and cytoplasm (see **Fig. 36-9A–B**).[71] In the variant translocations, often only cytoplasmic staining is observed (see **Fig. 36-9C–E**). In t(2;5)(p23;q35) translocation, the particular cytoplasmic, nuclear, and nucleolar staining can be explained by the formation of dimers between wild-type NPM and the fusion NPM-ALK protein. Wild-type NPM provides nuclear localization signals whereby the NPM-ALK protein can enter the nucleus.[71,72] The formation of NPM-ALK homodimers using dimerization sites at the N-terminus of NPM mimics ligand binding and is responsible for activation of the ALK catalytic domain (i.e., autophosphorylation of the tyrosine kinase domain of ALK), which is responsible for its oncogenic properties.

Besides t(2;5) translocation, at least 13 variant translocations involving the *ALK* gene at p23 have been recognized. In all these translocations the *ALK* gene is placed under the control of the

promoter of genes that are constitutively expressed in lymphoid cells resulting in expression of an *ALK* fusion gene. The most frequent variant translocation is t(1;2)(q25;p23),[61,62] in which the *TPM3* gene on chromosome 1 (which encodes a nonmuscular tropomyosin protein)[61] is fused to the *ALK* catalytic domain. However, in cases associated with the t(1;2) translocation, which express the TPM3-ALK protein (104 kDa), ALK staining is restricted to the cytoplasm of malignant cells, and in virtually all cases there is stronger staining on the cell membrane (see **Fig. 36-9C**).[55,61] This staining pattern is found in 15% to 20% of ALK-positive ALCLs. Tropomyosins are known to form dimeric alpha-coiled coil structures that can induce dimerization of the chimeric TPM3-ALK protein and activation of the ALK catalytic domain (i.e., autophosphorylation of ALK protein).[61] The genes fused with *ALK* in t(2;3)(p23;q11)[60,62] and inv(2)(p23q35)[64,65] have been identified (see **Fig. 36-9D**). Two different fusion proteins of 85 and 97 kDa (TFG-ALK_{short} and TFG-ALK_{long}) are associated with t(2;3)(p23;q11) translocation, which involves *TFG* (TRK-fused gene).[60] The inv(2)(p23q35) involves the *ATIC* gene (formerly known as *pur-H*), which encodes 5-aminomidazole-4-carboxamide-ribonucleotide transformylase-IMP cyclohydrolase (ATIC), which plays a key role in the de novo purine biosynthesis pathways.[64] In TFG-ALK-positive and ATIC-ALK-positive ALCLs, ALK staining is restricted to the cytoplasm in a diffuse pattern.[60,64]

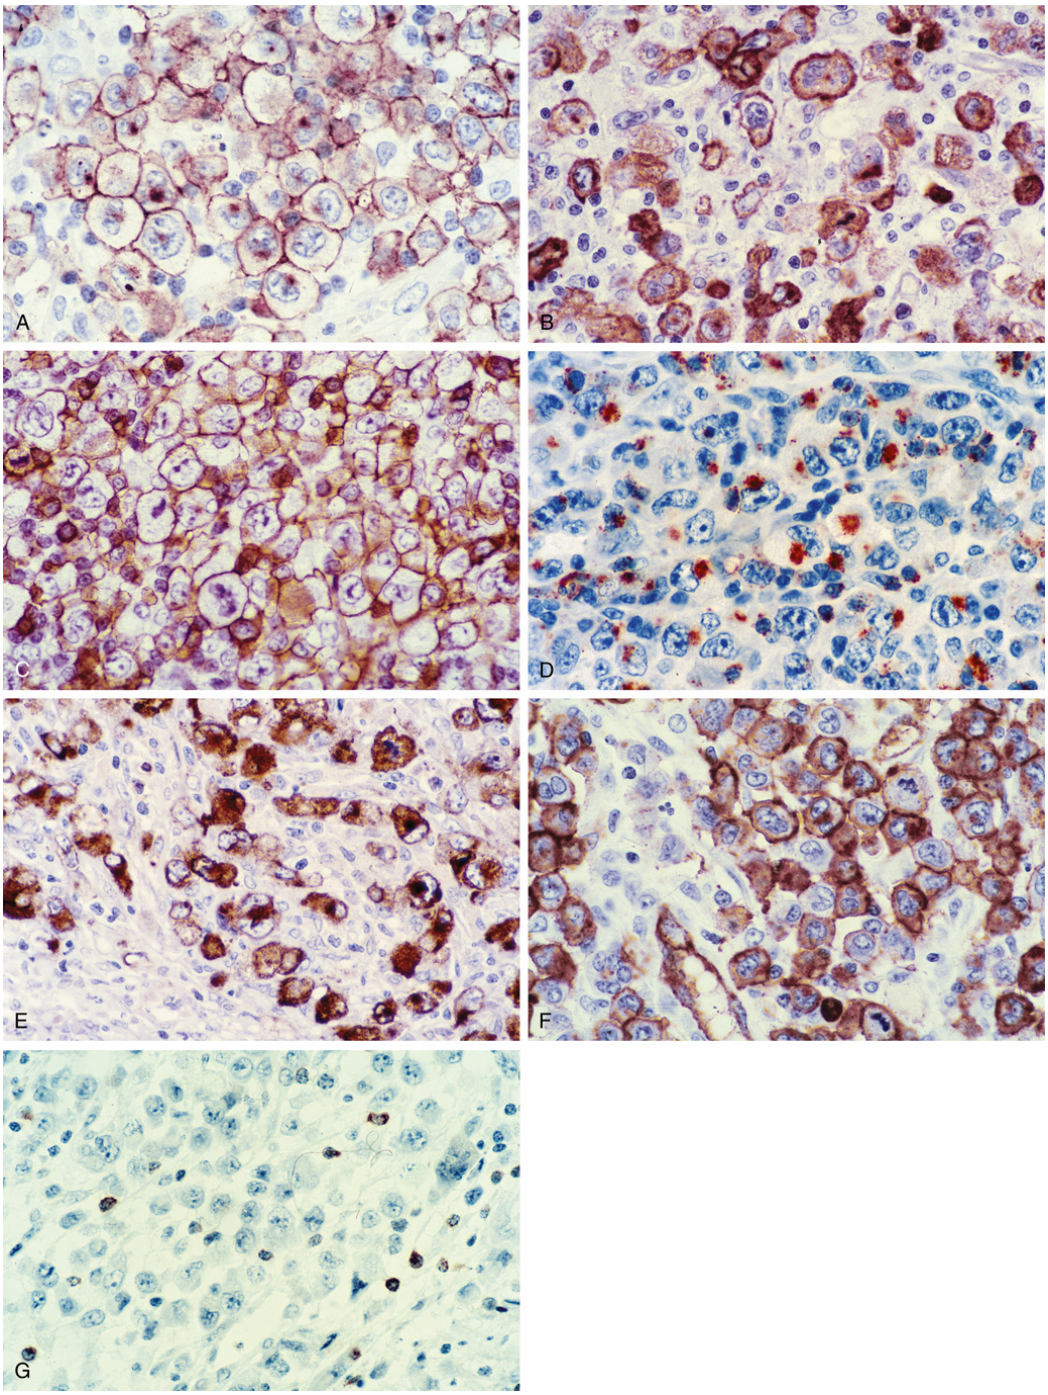

FIGURE 36-8 Immunophenotype of anaplastic large cell lymphoma (ALCL), common pattern. All malignant cells are strongly positive for CD30 **(A)** and for epithelial membrane antigen **(B)**. The majority of cases express the CD43 antigen **(C)**

and are positive for TIA-1 **(D)** and granzyme B **(E)**—proteins associated with cytotoxic granules. Neoplastic cells are usually positive for blood group antigens H and Y **(F)**, and most ALK-positive ALCLs are negative for BCL2 **(G)**. Note the positive small lymphocytes used as internal controls.

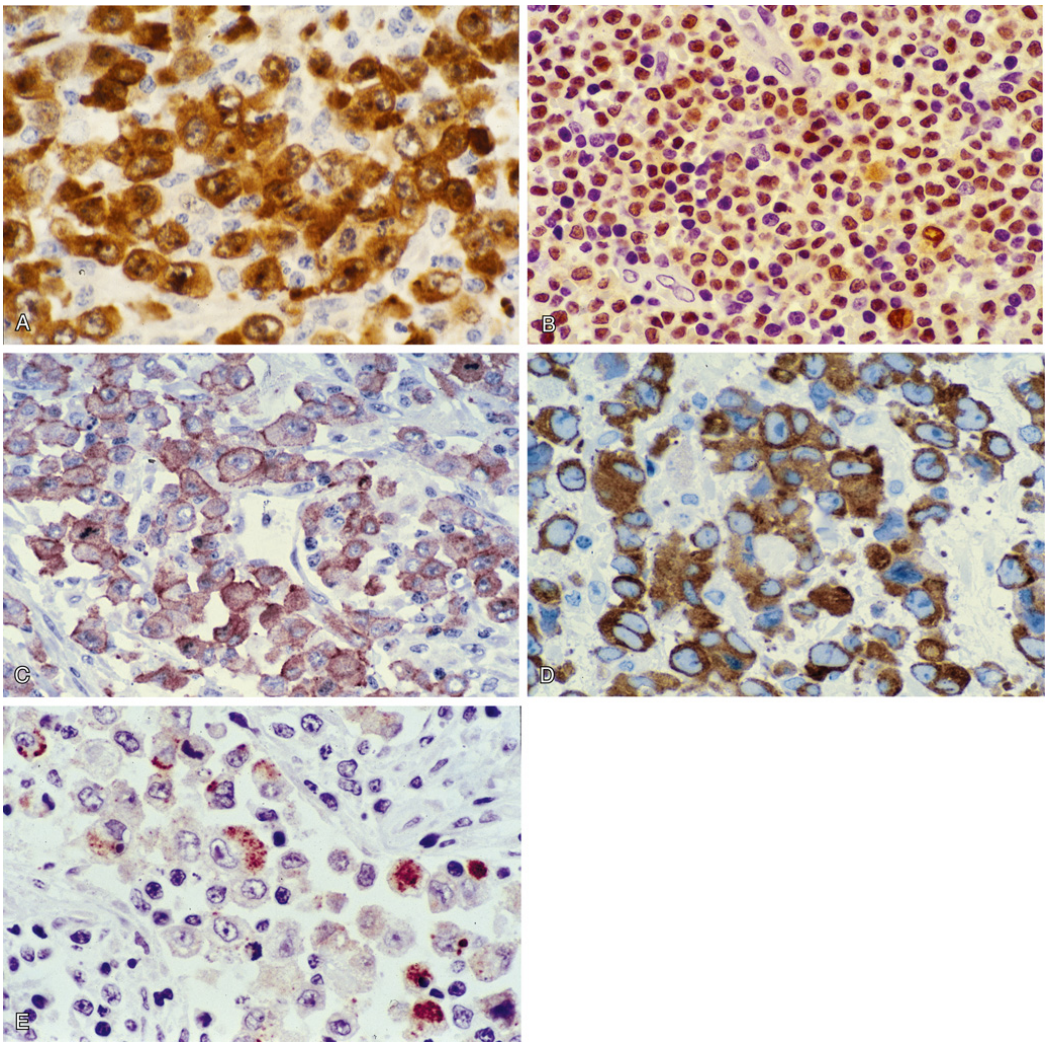

FIGURE 36-9 Anaplastic lymphoma kinase staining patterns.A, Nuclear, nucleolar, and cytoplasmic staining associated with the t(2;5) translocation (expression of NPM-ALK hybrid protein). **B,** In the small cell variant of anaplastic large cell lymphoma associated with the t(2;5) translocation, ALK staining is frequently restricted to nuclei. **C,** Restricted cytoplasmic staining with enhanced membrane staining in a case associated with the t(1;2) translocation (expression of TPM3-ALK hybrid protein). **D,**

Diffuse cytoplasmic staining in a case associated with the inv(2)(p23q35) (expression of ATIC-ALK). **E,** Finely granular cytoplasmic staining associated with the t(2;17) translocation (expression of CLTC-ALK hybrid protein).

Rare cases of ALCL show a unique granular ALK cytoplasmic staining pattern (see **Fig. 36-9E**).[63] In these cases, the *ALK* gene is fused to the *CLTC* gene, which encodes the clathrin heavy polypeptide (CLTC) that is the main structural protein of coated vesicles. The sequence of the fusion gene suggests that these tumors might have reciprocal translocations involving breakpoints at 17q11-qter and 2p23. In *CLTC-ALK*-positive ALCL, the presence of the clathrin heavy polypeptide in the hybrid protein accounts for the granular cytoplasmic staining pattern because the CLTC-ALK protein is involved in the formation of the clathrin coat on the surface of vesicles. Moreover, the process of clathrin coat formation mimics ligand binding; this allows the autophosphorylation of the carboxy-terminal domain of ALK protein, which is probably responsible for its oncogenic property.[63] In a single report, the moesin *(MSN)* gene at chromosome Xq11-12 was identified as a new *ALK* fused gene (MSN-ALK fusion protein) in a case of ALCL with a distinct ALK membrane-restricted pattern.[73] The particular membrane staining pattern of ALK is probably caused by the binding properties of the N-terminal domain of moesin to cell membrane–associated proteins. In this case, the *ALK* breakpoint was different from that described in all other translocations and occurred within the exonic sequence coding for the juxtamembrane portion of ALK. The *TRAF1-ALK* fusion encodes part, but not all, of the C-terminal TRAF domain responsible for

oligomerization of TRAF1.[68] Thus, the potential dimerization and function of TRAF1-ALK will require further study.[68]

Table 36-1

ALCL, Anaplastic large cell lymphoma; *ALK,* anaplastic lymphoma kinase; *ND,* not determined.

* Percentage of these variants in an unpublished series of 270 cases of ALK-positive ALCL.

In the translocation of dicentric (2;4)(p23;q33), the *ALK* partner was not identified.[74] *EEF1G* and *PABPC1* genes have been the most recent identified *ALK* gene partners.[69,70]

Whole-exome sequencing of ALK-positive ALCL has shown recurrent mutations in the T-cell receptor and Notch pathways, including potentially targetable, recurrent mutations of *NOTCH1*.[75]

Clinical Course and Prognostic Factors

The overall 5-year survival of ALK-positive ALCL varies from 70% to 80%, in contrast to less than 50% in ALK-negative cases.[76] Relapses are not uncommon (30% of cases), but they often remain sensitive to chemotherapy[77] and, in some cases, ALK small molecular inhibitors.[78] The International Prognostic Index appears to be of some value in predicting outcome, although less so than in other types of lymphoma.[29,79] An important prognostic indicator is ALK positivity, which has been associated with a favorable prognosis in series from North America, Europe, and Japan.[4,79,80] ALK positivity seems particularly important in patients more than 40 years old, whereas in patients less than 40 years old, ALK has no effect on progression-free survival and overall survival (OS).[81] No differences

have been found between NPM-ALK–positive tumors and tumors showing variant translocations involving *ALK* and fusion partners other than *NPM*.[80] In childhood ALK-positive ALCL, small cell or lymphohistiocytic morphologic features are adverse prognostic factors.[82,83] Detection of minimal disseminated disease by qualitative polymerase chain reaction (PCR) for *NPM-ALK* in bone marrow and peripheral blood at diagnosis and an early positive minimal residual disease (MRD) during treatment identify patients at risk of relapse.[84,85] This could be linked to poor immune control of the disease, partly reflected by the anti-ALK antibody titer that is inversely correlated to prognosis.[86] Quantification of early MRD might further improve risk stratification in international clinical studies and patient selection for early clinical trials.[87,88]

Anaplastic Large Cell Lymphoma, Alk Negative

Synonyms and Related Terms

WHO revised 4th ed.: Anaplastic large cell lymphoma, ALK-negative

WHO proposed 5th ed.: ALK-negative anaplastic large cell lymphoma

Tumors with morphologic and phenotypic features consistent with ALCL but negative for ALK have been recognized since the initial identification of *ALK* rearrangements and development of ALK immunohistochemistry. A challenge to defining these cases has been the lack of clear phenotypic or molecular markers to form the basis for strict diagnostic criteria. It was recognized, however, that these

cases showed distinct clinical features, with OS rates inferior to those of ALK-positive ALCL but superior to those of CD30-positive PTCL, NOS.[72] ALK-negative ALCL was first considered a provisional entity distinct from ALK-positive ALCL in the WHO 4th ed. and upgraded to a definite entity to the revised WHO 4th ed.[89] Ongoing study of ALK-negative ALCL has revealed additional molecular heterogeneity reflected in part by the recent International Consensus Classification (ICC) of hematopoietic neoplasms.[90]

Definition

ALK-negative ALCL has morphologic and phenotypic features indistinguishable from the common pattern of ALK-positive ALCL, with (1) hallmark cells; (2) a diffuse growth pattern, and (3) strong and uniform expression of CD30.[89] Desirable but not essential features include partial loss of T-cell markers, a cytotoxic phenotype, EMA positivity, and sinusoidal involvement. Unlike ALK-positive ALCL, histologic variants of ALK-negative ALCL are not recognized. ALK-negative ALCL with *DUSP22* rearrangement is now recognized as a genetic subtype of ALK-negative ALCL.

Epidemiology

Unlike ALK-positive ALCL, the incidence of ALK-negative ALCL peaks in adults (40–65 years),[10,82] with a slight male preponderance. The etiology of ALK-negative ALCL remains unclear. Occasional cases positive for EBV or arising in the setting of immunodeficiency have been reported, but most probably do not correspond stricto sensu to ALCL.[91,92] Cases arising in association with breast implants are considered a distinct entity and are discussed separately.

Clinical Features

Patients present with peripheral or abdominal lymphadenopathy or extranodal tumor; however, extranodal involvement is less common than in ALK-positive ALCL.[10] Secondary skin involvement by systemic ALK-negative ALCL must be distinguished from primary cutaneous ALCL, which presents in the skin and in some cases may involve locoregional lymph nodes. Occasional cases involve mucosal sites in the upper aerodigestive tract. Clinical staging is required in these cases as well, because lesions localized to these mucosal sites appear to behave more similarly to primary cutaneous ALCL than to systemic ALCL.[93,94]

Morphology

Morphologically, cases resemble the common pattern of ALK-positive ALCL, including hallmark cells that often grow within sinuses (**Fig. 36-10A**). Other cases consist of more pleomorphic cells with a high nuclear-to-cytoplasmic ratio (see **Fig. 36-10B–C**).[5,29,32,89] The classification of cases with morphologic features resembling CHL but of documented T-cell origin is controversial; some of these cases may best be classified as PTCL, NOS.[95] Cases with morphologic features resembling the small cell pattern of ALK-positive ALCL but lacking ALK expression are not included within ALK-negative ALCL because of the lack of phenotypic or molecular markers that allow distinction from CD30-positive PTCL, NOS.

Immunophenotype

CD30 staining should be strong and uniform, and typically shows both a membranous and Golgi pattern. A diagnosis of PTCL, NOS should be considered in cases with variable CD30 expression. An

exception is in patients with known ALCL treated with the anti-CD30 immunoconjugate brentuximab vedotin, in which diminished CD30 expression may be seen.[96,97] More than half of cases express one or more T-cell markers.[79] Positive staining for CD3 is more common than in ALK-positive ALCL. CD2 and CD4 are positive in a significant proportion of cases, whereas CD8-positive cases are rare. As in ALK-positive ALCL, the loss of one or more T-cell markers is frequently noted. In cases with a null-cell phenotype, a diagnosis of CHL rich in neoplastic cells must be excluded. PAX5, positive in 95% of CHL cases, is a useful marker in this setting; however, occasional ALCLs express PAX5 and molecular studies should be performed in ambiguous cases.[98] Expression of EMA is variable. The cytotoxic-associated markers TIA-1, granzyme B, and perforin are found in many cases, but are typically negative in the presence of *DUSP22* rearrangements (**Fig. 36-11**).[99] Almost all ALK-negative ALCL with *DUSP22* rearrangement show a strong expression of LEF1, a transcription factor of the Wnt/β-catenin pathway that may serve as surrogate marker.[100] ALK-negative ALCL is consistently negative for EBV (i.e., EBER and LMP-1).[43]

Genetics and Molecular Findings

TR genes are clonally rearranged in most cases, regardless of whether they express T-cell antigens. ALK-negative ALCL differs from both PTCL, NOS and ALK-positive ALCL in chromosome losses and gains.[101,102] Patients with ALK-negative ALCL and complex chromosomal abnormalities have significantly shorter OS.[103] About two-thirds of ALK-negative ALCLs show activation of the JAK-STAT3 signaling pathway, attributable in some cases to mutations in *JAK1* or *STAT3,* or fusions involving *ROS1, TYK2,* or *FRK*.[104,105] Recurrent

rearrangements (R) of the *DUSP22-IRF4* locus on 6p25.3 (*DUSP22*-R) (**Fig. 36-11F**) or the *TP63* locus on 3q28 (*TP63*-R) have been reported in 30% and 8% of ALK-negative ALCLs, respectively.[99,106,107] *DUSP22*-R is associated with decreased expression of the dual-specificity phosphatase gene, *DUSP22,*[106] a putative tumor suppressor that inhibits T-cell receptor signaling.[108] The most common rearrangement, seen in 45% of cases, is t(6;7)(p25.3;q32.3) and is associated with downregulation of microRNAs in the MIR29 cluster on 7q32.3.[109] ALK-negative ALCL with *DUSP22*-R is considered a distinct genetic subtype of ALK-negative ALCL in the new ICC classification based on unique clinicopathologic and molecular features, including characteristic morphologic and phenotypic features, unique transcriptomic profile, DNA hypomethylation, and recurrent mutations of the *MSC* gene.[90,110-112] *TP63*-R occurs most commonly with the *TBL1XR1* gene as inv(3)(q26q28) and leads to expression of fusion proteins sharing homology with oncogenic ΔNp63 isoforms.[107] *DUSP22*-R and *TP63*-R are not specific for ALCL and their utility in diagnosing ALK-negative ALCL has not been established; however, they have significant prognostic associations. Occasional cases may show dual *DUSP22*-R and *TP63-R*.[113] The molecular signature of ALK-negative ALCL includes overexpression of *CCR7, CNTFR, IL22,* and *IL21* genes but does not identify the underlying oncogenic mechanism associated with these tumors.[50] In addition, these results do not provide definitive evidence of whether ALK-negative ALCL is more closely related to ALK-positive ALCL or to PTCL, NOS.[50,114,115] Recently, gene expression profiling studies have indicated that ALK-negative ALCL and PTCL, NOS have distinct molecular signatures, and may be

differentiated by as few as three genes (*TNFRSF8, BATF3,* and *TMOD1*).[116,117]

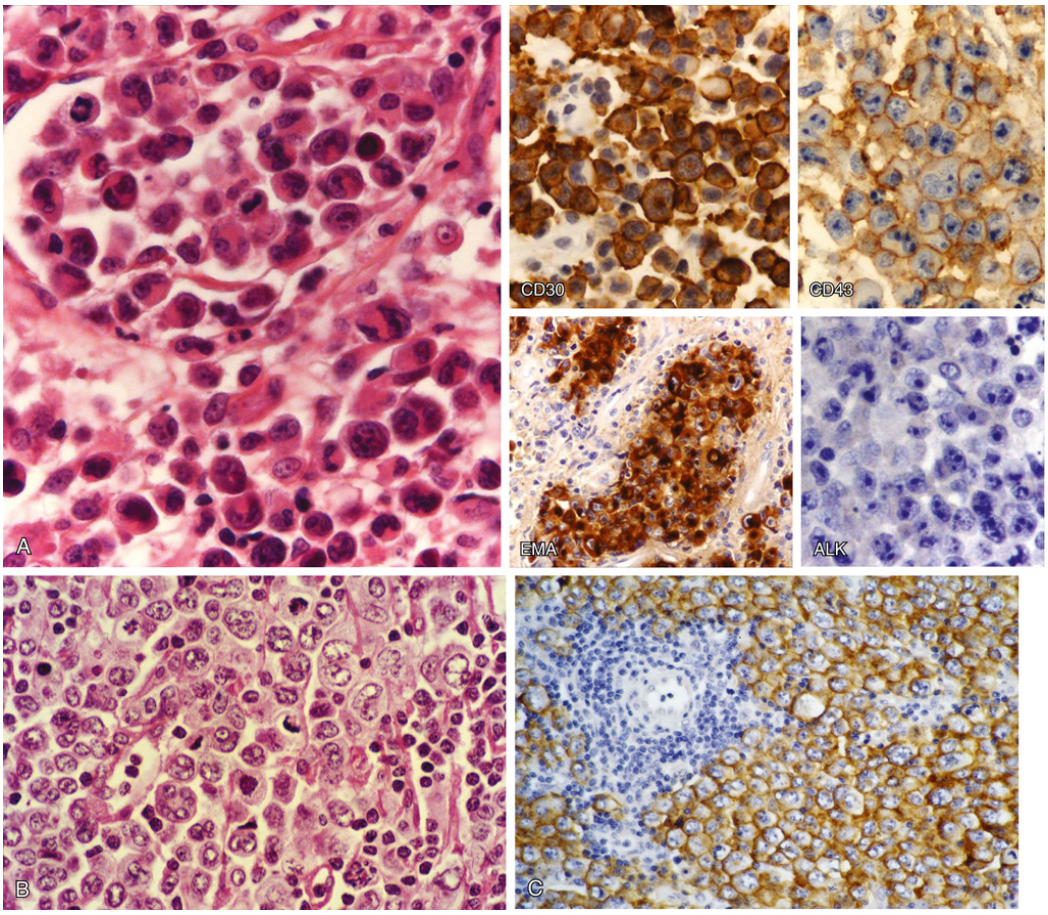

FIGURE 36-10 **A,** Anaplastic large cell lymphoma, anaplastic lymphoma kinase (ALK)-negative showing morphologic and phenotypic features closely comparable to those observed in ALK-positive ALCL. ALK staining was repeated twice and proved to be negative. Numerous hallmark cells grow within sinuses. The immunophenotype is similar to that of ALK-positive ALCL in most respects: CD30 positive, epithelial membrane antigen (EMA) positive, perforin positive, CD43 positive, CD2 positive. **B–C,** ALK-negative ALCL consisting of more pleomorphic cells with a high nuclear-to-

cytoplasmic ratio, strongly positive for CD30. The case shown in **B** was of T phenotype (CD3 positive and CD4 positive) but negative for EMA.

Clinical Course and Prognostic Factors

Overall, the clinical outcome of conventionally treated ALK-negative ALCL is poorer than that of ALK-positive ALCL.[118] In a study by Savage and coworkers,[79] the 5-year OS of patients with ALK-negative ALCL was 49% compared with 70% for those with ALK-positive ALCL; PTCL, NOS with high CD30 expression, which can be difficult to differentiate histologically from ALK-negative ALCL, had a poorer prognosis (5-year OS of 19%). Recent data indicate, however, that outcomes of ALK-negative ALCL vary markedly based on genetic subtype.[99,119] In the largest study to date, ALK-negative ALCLs with *DUSP22*-R had a 5-year OS of 90%, similar to that of ALK-positive ALCL. ALK-negative ALCLs with *TP63*-R had a 5-year OS of 17%, while ALK-negative ALCLs lacking *DUSP22*-R, and *TP63*-R had a 5-year OS of 42%. Genomic losses of *TP53* or *PRDM1* also are associated with poor outcomes.[120]

Breast Implant–Associated Anaplastic Large Cell Lymphoma

Synonyms and Related Terms

WHO revised 4th ed.: Breast implant-associated anaplastic large cell lymphoma

WHO proposed 5th ed.: Breast implant-associated anaplastic large cell lymphoma

Definition

Breast implant–associated anaplastic large cell lymphoma (BIA-ALCL) is a rare form of ALCL identified as a provisional entity in the revised WHO 4th ed. ICC and the WHO 5th ed. classification has upgraded it to a definite entity.[90] The first case of BIA-ALCL was described in 1997 by Keech and Creech[121] and subsequently, more than 800 cases of BIA-ALCL have been reported in the literature.[122-126]

Etiology

BIA-ALCL is a multifactorial disease, which involves several intrinsic or extrinsic factors.[126] Among them, several studies have implicated high-textured implants and chronic inflammation caused by implant debris and material leached from the bacterial biofilm.[127-129] In addition, an HLA polymorphism (HLA-A∗26 antigen) might also increase the risk of BIA-ALCL.[130] Together with the acquisition of mutations or other molecular alterations, these factors are thought to contribute to a clonal expansion of T lymphocytes and lead to BIA-ALCL development.

Epidemiology

The risk of developing BIA-ALCL is very low. The incidence of BIA-ALCL varies from 1/30,000 to 1/1000 women with breast implants, with approximately 660 cases reported to the FDA.[131-133] De Jong D et al. estimated the risk at 0.1 to 0.3 per 100,000 women-years with prostheses.[122] In the French *Lymphopath* network, since 2010, three to four new cases per year have been observed for 340,000 women with prostheses. Interestingly, in the latter series, BIA-ALCL was and still is the most frequent breast T-cell lymphoma.[134]

Clinical Features

The mean age of the patients is 61 years (range 28–87 years) and the mean time elapsed between placement of breast implants and diagnosis of BIA-ALCL is 10 years (range 1–32 years).[123,124,135]

Most BIA-ALCL patients (80%) present with seroma, which is a clinical term used to identify accumulation of fluid around the breast implant.[122,123,135,136] In contrast, a minority of patients (20%) have a palpable tumor mass, generally limited to the breast or associated with axillary lymphadenopathy.[122,135,136] Some patients present with a breast tumor mass associated with seroma.[137]

Morphology

The diagnosis of BIA-ALCL is based on cytologic analysis of a periprosthetic effusion or histologic analysis of capsule associated with immunohistochemistry panel, including T cell markers and CD30.[138] Histopathologic examination shows two clearly different types of proliferations.

In patients with a seroma, the proliferation is often confined to the luminal surface with early capsular invasion or not. In the latter case,

tumor cells are restrained to luminal surface without invading the capsule and defined the so-called *"in situ"* BIA-ALCL form (**Fig. 36-12A**). However, the distribution of malignant cells on the inner side of the capsule is usually heterogeneous, with some cellular areas and other areas with only fibrous tissue and almost no cells. The proliferation consists of a population of large pleomorphic cells of varying size suggesting a large cell lymphoma, although scattered hallmark-like cells may be observed (**Fig. 36-12B**). Some neoplastic cells are found to be encased within fibrinoid material. Of note, in seromas, neoplastic cells may be identified in cell suspension.

Patients presenting with a tumor mass show more heterogeneous proliferations, infiltrating surrounding tissues (so-called "tumor-type" BIA-ALCL).[134] They consist of either sheets or clusters of large anaplastic cells accompanied by large numbers of eosinophils. In some cases, the presence of numerous RS-like cells in a background rich in eosinophils may be highly suggestive of CHL (Hodgkin-like feature) (**Fig. 37-12C**).[123,135] In tumor-type BIA-ALCL, necrosis or sclerosis may be observed.[135] In occasional cases, the two morphologic patterns (i.e., *in situ* and tumor-type BIA-ALCL) are observed. In the latter cases, besides a proliferation confined to the fibrous capsule, one sees a focally bulging proliferation that invades the surrounding tissue (**Fig. 36-12D**). Such an association suggests that lesions confined to the capsule may, with time, evolve to a proliferation invading surrounding tissue.

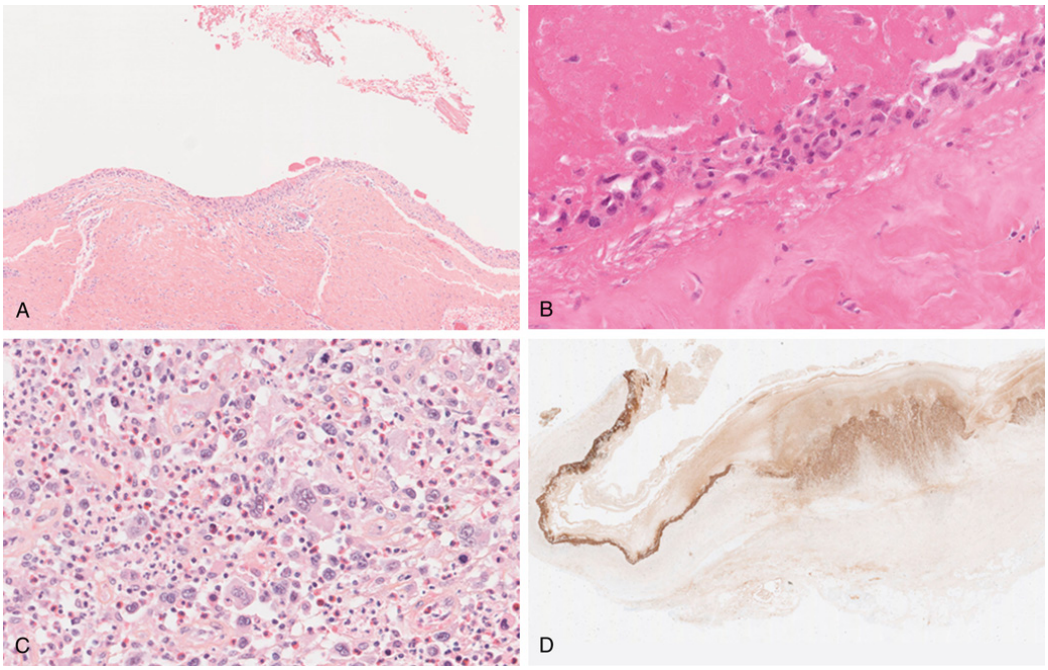

FIGURE 36-12 **A,** Breast implant–associated anaplastic large cell lymphoma (BIA-ALCL) confined to the fibrous capsule of a patient who presented with seroma around the implant. **B,** High magnification shows large pleomorphic cells with rare hallmark-like cells. **C,** This tumor mass infiltrated the capsule and the pectoral muscle. On higher magnification, one sees a population of pleomorphic noncohesive cells. As seen in ALCLs, some atypical cells with crown-like or kidney-shaped nuclei are observed. Reed-Sternberg-like cells are also observed, which, in association with large number of eosinophils, may mimic a classic Hodgkin lymphoma. **D,** In occasional cases, the two morphologic patterns (i.e., *in situ* and tumor-mass BIA-ALCLs) are observed. Immunostaining with CD30/Ber-H2 staining highlights a

proliferation confined to the fibrous capsule and a focally bulging proliferation that invades the surrounding tissue.

Immunophenotype

Malignant cells are strongly positive for CD30 and their distribution along the inner side of the capsule is better seen after CD30 staining (**Fig. 36-12D**).[123] These cells show variable positive staining for EMA.[123,125] In the majority of cases, neoplastic cells are of T-cell phenotype and positive for one or several T-cell markers (i.e., CD2, CD3, CD4, CD43) and cytotoxic-associated markers (TIA-1, granzyme B, or perforin).[123,125,137] CD45/LCA is positive in approximately one-third of cases.[137] BIA-ALCL are consistently negative for EBV (i.e., EBER and LMP1).[123,125] Of note, only one case of breast implant–associated lymphoma was positive for EBV but this particular case was diagnosed as extranodal NK/T-cell lymphoma.[139] In all reported cases, ALK staining was negative. If positive, secondary breast involvement by a systemic ALK-positive ALCL must be suspected (personal observation). Tumor cells frequently express PDL1 and nuclear phospho-STAT3 (p-STAT3) indicative of a role of STAT3 constitutive activation in BIA-ALCL.[134,140,141]

Genetics and Molecular Findings

TR γ genes are clonally rearranged in the majority of cases. However, false negatives can occur, particularly when the number of neoplastic cells is low as frequently observed in the in situ BIA-ALCL subtype.[123,137,142] BIA-ALCLs are negative for *ALK, DUSP22,* and *TP63* gene rearrangements.[141] Copy number aberration (CNA)

analysis of BIA-ALCL has identified recurrent alterations including gains on chromosomes 2p, 9p, and 20, and losses on 8p and 20. Interestingly, loss at chromosome 20q13.13 has been considered a specific genomic feature of BIA-ALCL, distinguishing them from other classes of ALCL.[143] Genomic sequencing showed recurrent mutations in the JAK-STAT pathway in up to 60% of BIA-ALCL cases, including activating mutations of *STAT3, JAK1, STAT5B,* and alterations of negative regulators like *SOCS3, SOCS1,* and *PTPN1*.[140,144-146] Whole exome sequencing of the largest series of BIA-ALCL has also reported recurrent mutations of epigenetic modifiers in 74% of cases, involving notably *KMT2C, KMT2D, CHD2,* and *CREBBP* genes.[140] Both somatic and germline mutations in *TP53* have been found in BIA-ALCL.[140,144-146] Finally, one study reported an increased risk of BIA-ALCL in patients with germline mutations of *BRCA1* or *BRCA2*.[147] Genomic expression profiling showed that BIA-ALCLs exhibit an activated CD4-positive memory T-cell phenotype with upregulation of genes involved in cell motility (*CCR6, MET,* and *CXCL14*) and higher expression of *RORC1* and *IL17A* compared with normal CD4-positive T cells.[148] In the same study, the authors also found an overexpression of genes involved in myeloid cell differentiation (e.g., *PPARG* and *JAK2*) and genes encoding for ribosomal proteins *(RPS10, RPS19, RPL17, RPL18)* in which *RPS10* was one of the most differentially expressed genes between BIA-ALCL and other PTCLs.[148]

Finally, though BIA-ALCL and other ALCLs share a common activation of JAK/STAT pathway with downregulation of TCR signaling, BIA-ALCL is more enriched in regulatory T cell–related genes and exhibits a dramatic upregulation of hypoxia signaling

genes such as *carbonic anhydrase 9 (CA9), VEGFA, VEGFB,* and *SLC2A3* compared with other ALCLs.[149]

Clinical Course and Prognostic Factors

Capsulectomy with margin evaluation is the optimal treatment for most cases of BIA-ALCL. The use of MD Anderson TNM staging from T1 to T4 is highly recommended.[150] T1 (so-called "in situ" BIA-ALCL) indicates a seroma or tumor cells confined to the luminal capsule only. T2 indicates early capsular invasion. T3 indicates tumor cell aggregates or sheets within the capsule, whereas T4 indicates that tumor cells are beyond the capsule. Nodal involvement refers to the presence of tumor cells in one (N1) or multiple (N2) regional lymph nodes. M1 is notified when the disease spreads to other organs or distant sites. Patients with stage I disease (T1-T3 N0 M0) who are treated with implant removal and total capsulectomy have excellent outcomes.[123-125,135-137] In contrast, patients with II-IV stage disease (T4 N0 M0; T1-T4 N1-2 M0-1) had a more aggressive clinical course.[124,135-137] In the latter cases, systemic therapy with anthracycline-based regimen or brentuximab-vedotin is recommended.[134,135,150,151] Additionally, chest wall radiotherapy should be considered in cases of incomplete resection (even for T1 and T2 stages) or with chest wall infiltration.

Differential Diagnosis of Anaplastic Large Cell Lymphoma

Even if the morphologic features of most ALCLs suggest the diagnosis, a definitive diagnosis cannot be made without immunohistochemistry. A major advance was made with the

production of ALK1 and ALKc antibodies.[27,55] They are of critical diagnostic value in some ALK-positive ALCLs with unusual morphologic features. The diagnosis of ALK-negative ALCL is more difficult because of the lack of specific markers. Therefore, all tumors consisting of large cells expressing the CD30 antigen need to be considered in the differential diagnosis (**Table 36-2**).

Anaplastic Large Cell Lymphoma, Common Pattern

ALCL, common pattern is easy to recognize in children. In adults, the main differential diagnoses are metastatic malignancies because the majority of these ALCL cases exhibit a sinusoidal growth pattern. However, undifferentiated carcinomas usually express cytokeratin and EMA and are negative for the CD30 antigen. We have observed rare cases of carcinomas that are weakly positive for CD30. Conversely, occasional ALCLs may express cytokeratins.[152] Metastasis from a melanoma may simulate ALCL, but most of these tumors are S-100^{+}, HMB45^{+}, PNL2^{+}, EMA$^{-/+}$, and CD30^{-}; however, rare cases positive for CD30 have also been reported.[153] Embryonal carcinoma expresses CD30, but morphologically does not resemble ALCL.[154] The most difficult problem in the differential diagnosis is PTCL, NOS with a predominant population of large cells, sometimes infiltrating lymphatic sinuses. Some of these tumors strongly express CD30 and may be positive for EMA.[155] However, the staining for CD30 is typically more variable in intensity or lacks the usual membranous and Golgi pattern characteristic of ALCL. Nevertheless, the distinction between PTCL, NOS and ALK-negative ALCL is not always clear-cut, and it is preferable to diagnose ALK-negative ALCL only if both the morphology and the phenotype are close to those of ALK-positive ALCL.[89] Extranodal nasal-type NK/T-cell lymphoma

and enteropathy-associated T-cell lymphoma also may show a varying proportion of tumor cells expressing CD30.[9] Diffuse large B-cell lymphomas with anaplastic morphology may show the morphologic features, including a sinusoidal growth pattern, and the phenotypic features (CD30 positivity) of ALCL. However, these tumors express B-cell antigens, and t(2;5) is absent.[156]

Table 36-2

Differential Diagnosis of Anaplastic Large Cell Lymphoma

Entity	Phenotype of Neoplastic Cells	Comments
ALCL, common type	$CD30^{+}$, EMA^{+}, ALK^{+} (85%), $CD45^{-/+}$, $CD3^{-/+}$, $CD43^{+}$, $CD2^{-/+}$, $CD4^{-/+}$, $CD5^{-/+}$, $CD7^{-/+}$, $CD8^{-/+}$, cytotoxic proteins*$^{+/-}$, $BCL2^{-}$ (most cases)	Sinusoidal growth pattern “Hallmark” cells
Metastatic malignancy		
Carcinoma	Cytokeratin^{+}, EMA^{+}, $CD30^{-}$, $CD45^{-}$	Rare cases CD30-positive
Melanoma	S-100^{+}, $EMA^{-/+}$, $HMB45^{+}$,	Weak CD30 staining has been reported

Entity	Phenotype of Neoplastic Cells	Comments
	PNL2^{+}, CD45^{-}	
PTCL, NOS with predominantly large cells	CD30$^{-/+}$, EMA$^{-/+}$, ALK^{-}, CD3^{+}, CD2$^{-/+}$, CD4$^{-/+}$, CD5$^{-/+}$, CD7$^{-/+}$, CD8$^{-/+}$, cytotoxic proteins*$^{+/-}$, BCL2^{+}	Rare cases with sinusoidal growth pattern and pleomorphic cells
DLBCL		
ALK+ DLBCL	CD30^{-}, EMA^{+}, ALK^{+}, CD20/CD79a^{-}, CD138^{+}, cytoplasmic IgA (most cases)	Sinusoidal growth pattern Immunoblast or plasmablastic cells
DLBCL, anaplastic variant†	CD30$^{-/+}$, EMA$^{-/+}$, ALK^{-}, CD20/CD79a^{+}	Some show a sinusoidal growth pattern but are ALK^{-}

Entity	Phenotype of Neoplastic Cells	Comments
Histiocytic sarcoma	$CD30^-$, EMA^-, ALK^- (most cases), $CD68^+$, $CD163^+$, $lysozyme^+$	
ALCL, lymphohistiocytic	$CD30^+$, EMA^+, ALK^+, $CD68^-$, $CD45^{-/+}$, $CD3^{-/+}$, $CD43^+$, $CD2^{-/+}$, $CD4^{-/+}$, $CD5^{-/+}$, $CD7^{-/+}$, $CD8^{-/+}$, cytotoxic proteins*$^{+/-}$	Sinusoidal growth pattern may be absent, but perivascular pattern is observed in all cases Only reactive histiocytes are $CD68^+$
Lymphadenitis rich in histiocytes	$CD30^-$, EMA^-, ALK^-	Rare $CD30^+$ immunoblasts No perivascular pattern
ALCL, small cell variant	$CD30^+$, EMA^+, ALK^+, $CD45^{-/+}$, $CD3^+$ (most cases),	Sinusoidal growth pattern may be absent, but

Entity	Phenotype of Neoplastic Cells	Comments
	$CD43^+$, $CD2^{+/-}$, $CD4^{+/-}$, $CD5^{+/-}$, $CD7^{+/-}$, $CD8^{+/-}$, cytotoxic proteins*$^+$	perivascular pattern is observed in all cases Restricted nuclear ALK staining
PTCL, NOS with small-to-medium-sized cells	$CD30^{-/+}$, $EMA^{-/+}$, ALK^-, $CD45^{+/-}$, $CD3^+$ (most cases), $CD43^+$, $CD2^{-/+}$, $CD4^{-/+}$, $CD5^{-/+}$, $CD7^{-/+}$, $CD8^{-/+}$, cytotoxic proteins*$^{+/-}$	Scattered $CD30^+$ cells may be observed, but without perivascular pattern
ALCL, other‡	$CD30^+$, EMA^+, ALK^+, $CD45^{-/+}$, $CD3^{-/+}$, $CD43^+$, $CD2^{-/+}$, $CD4^{-/+}$, $CD5^{-/+}$,	Sinusoidal growth pattern "Hallmark" cells Rare cases of ALK^+ ALCL may show $CD15^+$

Entity	Phenotype of Neoplastic Cells	Comments
	$CD7^{-/+}$, $CD8^{-/+}$, cytotoxic proteins*$^{+/-}$, $BCL2^{-}$ (most cases)	paranuclear staining
Classic Hodgkin lymphoma	$CD30^{+}$, EMA^{-}, $CD15^{+/-}$, ALK^{-}, $CD45^{-}$, $CD3^{-}$, $PAX5^{+}$ weak, $CD43^{-}$, $CD20^{-/+}$ (heterogeneous staining), EBV/LMP-$1^{+/-}$ (60%), BCL2 variable	Rare sinusoidal growth pattern No perivascular pattern
Inflammatory myofibroblastic tumors	$CD30^{-}$, EMA^{-}, ALK^{+} (cyt)	ALCL with sarcomatous morphology is always $CD30^{+}$, EMA^{+}, and ALK^{+}
Rhabdomyosarcoma	$CD30^{-}$, EMA^{-}, $ALK^{-/+}$ (cyt), $desmin^{+}$	Rare cases of rhabdomyosarcoma may show rare

† Rare cases of DLBCL show a predominant sinusoidal growth pattern but are negative for ALK.

‡ Includes giant cell, sarcomatous, hypocellular; rare cases may resemble Hodgkin lymphoma at low-power magnification.

Two additional tumors deserve attention. The first is ALK-positive large B-cell lymphoma, which is now considered a distinct entity.[56] Morphologically, these tumors are composed of monomorphic large plasmablast-like or immunoblast-like cells with large central nucleoli, and often invade lymphatic sinuses (**Fig. 36-13A–B**). At low magnification, these tumors resemble ALCL, but they lack CD30. These lymphomas strongly express EMA (see **Fig. 36-13C**), as does ALCL, but they also contain intracytoplasmic immunoglobulin (usually IgA) of a single light chain type. They often lack lineage-associated leukocyte antigens (CD3, CD20, CD79a), except for CD4 and CD57 in some cases. These tumors weakly express or may even be negative for the leukocyte common antigen CD45. Occasional cases are positive for cytokeratin, which, in addition to EMA positivity and weak or negative staining for CD45, may lead to the

misdiagnosis of carcinoma. Characteristically, lymphoma cells are strongly positive for ALK. In most cases, the staining is restricted to the cytoplasm and is granular, indicating an association with CLTC-ALK protein.[34,157] ALK-positive diffuse large B-cell lymphoma typically follows an aggressive course. Other lymphomas exhibiting a sinusoidal growth pattern, such as so-called “microvillous” lymphomas, may be either negative or positive for CD30.[158,159] However, these tumors are relatively easy to recognize by immunohistochemistry because they express B-cell antigens (CD20 and CD79a) and are negative for ALK.

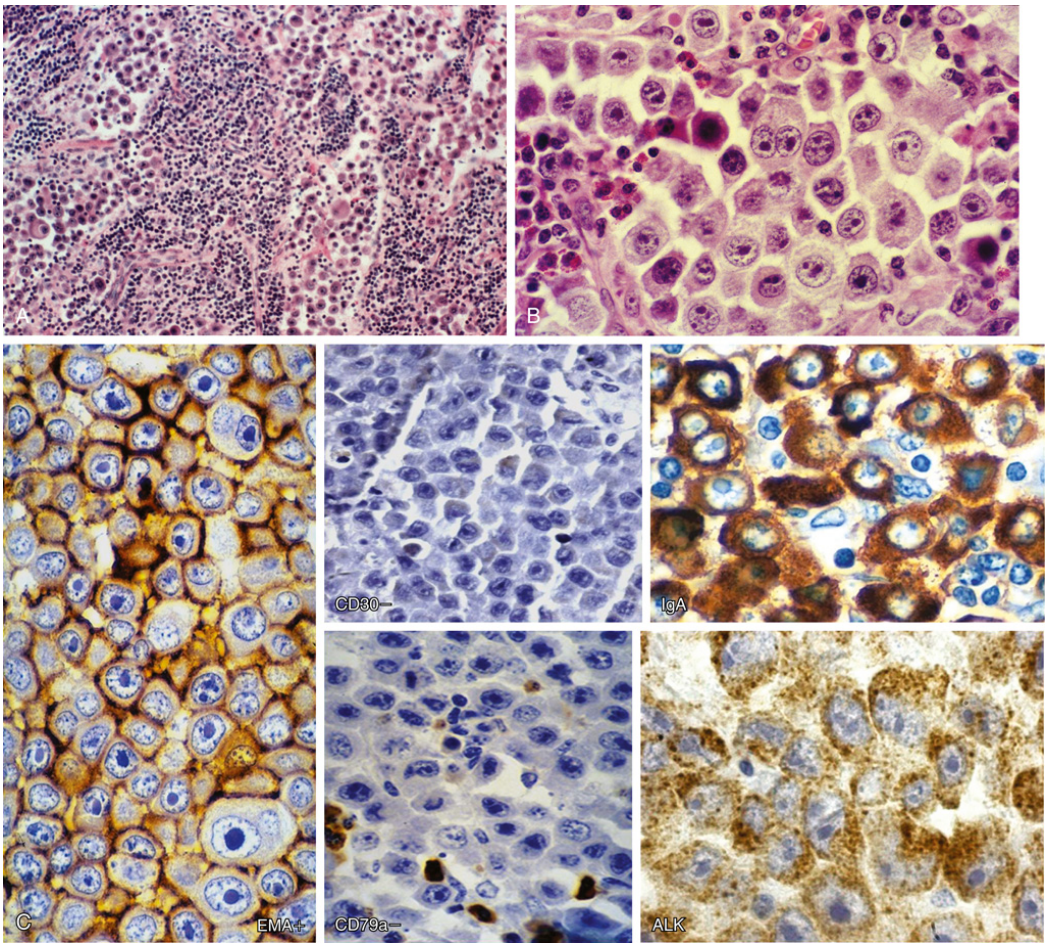

FIGURE 36-13 Anaplastic lymphoma kinase (ALK)–positive diffuse large B-cell lymphoma exhibiting a sinusoidal growth pattern **(A)** with large immunoblastic or plasmablastic cells **(B)**. The composite figure **(C)** illustrates the phenotype of lymphoma cells that are strongly positive for epithelial membrane antigen (EMA), negative for CD30 and B-cell–associated antigens (including CD79a), and usually immunoglobulin A (IgA) positive and show a cytoplasmic granular ALK staining.

The second type of tumor deserving attention is the true histiocytic tumor, which is extremely rare. In a report based on the study of more than 900 lymphomas, there were only four true histiocytic tumors.[160] Histiocytic sarcomas usually consist of large cells with moderate or abundant cytoplasm and pleomorphic nuclei with prominent nucleoli. Morphologically malignant-appearing cells are positive for CD68 (KP1 and PGM1) and CD163, macrophage-associated antigens, and for lysozyme. Like normal histiocytes or macrophages, true histiocytic sarcomas react with CD4 but are negative for all other T-cell and B-cell markers. These cells are negative for CD1a and PS100. Recognition of these tumors is important because of their poor prognosis in the majority of cases. Similar morphologic and phenotypic features are seen in monoblastic leukemias, which can be distinguished from histiocytic sarcomas in part by clinical presentation (i.e., bone marrow involvement). Rare cases of aggressive mastocytosis may consist of large cells reminiscent of hallmark cells and express the CD30 antigen. They are positive for CD117, CD4, and CD68 antigens. Acid toluidine blue shows the characteristic metachromatic granules, but in malignant cases, granularity may be sparse. Immunohistochemistry for mast cell tryptase is the preferred diagnostic tool.[161]

Anaplastic Large Cell Lymphoma, Lymphohistiocytic Pattern

ALCL, lymphohistiocytic pattern may be extremely difficult to recognize and is commonly misdiagnosed as histiocyte-rich lymphadenitis. One must keep in mind that the lymph node architecture is obliterated in these lesions, a feature that is rare in reactive processes. As described, malignant cells are difficult to

identify because they are obscured by large numbers of reactive histiocytes associated with varying numbers of plasma cells. The key to the diagnosis is immunohistochemistry using CD30 and ALK-reactive antibodies; this highlights the malignant cells scattered among the histiocytes and typically concentrated around blood vessels.[11,162]

Anaplastic Large Cell Lymphoma, Small Cell Pattern

ALCL, small cell pattern is commonly misdiagnosed as PTCL, NOS. Hallmark cells are present but are difficult to detect among small-to-medium-sized cells. Although the majority of small-to-medium-sized lymphoid cells are malignant, they usually express CD30 and EMA weakly, which makes the diagnosis even more difficult. By contrast, large cells strongly express CD30 and ALK and are localized around blood vessels. As noted, a small cell variant of ALK-negative ALCL is not recognized in the revised WHO 4th ed. classification, and T-cell lymphomas showing these morphologic features should be diagnosed as PTCL, NOS.

Anaplastic Large Cell Lymphoma, Hodgkin-Like Pattern

ALCL, Hodgkin-like pattern, mimicking nodular sclerosis CHL, exists but is extremely rare. This diagnosis requires positive staining for ALK.[37] True CHL rich in neoplastic cells must be excluded in ALK-negative cases, bearing in mind that CHL of documented B-cell lineage may express T-cell antigens.[163] Some tumors with Hodgkin-like features, including expression of CD15 and CD30, but of documented T-cell lineage are most appropriately diagnosed as PTCL, NOS rather than ALCL if they are ALK negative.[95] Recently,

JAK2-R has been identified in some cases with these features, though it remains unclear whether this finding can be used to aid in the differential diagnosis between ALK-negative ALCL and PTCL, NOS.[164]

Anaplastic Large Cell Lymphoma, Sarcomatous Pattern

ALCL, sarcomatous pattern may simulate lymph node involvement by a soft tissue tumor or even Kaposi sarcoma. However, in the sarcomatous pattern of ALCL, one observes typical features of ALCL in at least some areas. Because ALCL can present as a soft tissue or bone mass, the diagnosis should be considered in a soft tissue sarcoma in a child or young adult. The differential diagnosis is complicated by ALK protein expression in rhabdomyosarcoma and ALK-positive inflammatory myofibroblastic tumor.

ALK-Positive Nonlymphoid Tumors

ALK-positive nonlymphoid tumors may be responsible for diagnostic difficulties. Overall, ALK expression can be considered highly indicative of ALCL. However, as originally reported by Morris and colleagues,[3] rhabdomyosarcoma occasionally expresses the full-length (200 kDa) ALK protein (**Fig. 36-14A–B**). Some inflammatory myofibroblastic tumors are associated with *ALK* gene rearrangement at 2p23 (see **Fig. 36-14C–D**). Chan and coworkers[57] described a novel form of ALK-positive histiocytosis occurring in infants. The authors concluded that ALK-positive histiocytosis is a distinct histiocytic proliferative disorder that typically resolves slowly but can be life-threatening during the active phase. A more recent study based on 39 cases expanded the clinicopathologic spectrum of ALK-

positive histiocytosis.[165] The *KIF5B-ALK* fusion was the most frequently observed in these tumors. They can occur both in infants and adults, and can present with single-system or multisystemic disease, with frequent neurologic involvement.[165] ALK-positive histiocytosis is now considered a separate histiocytic entity in the ICC classification distinct from Erdheim-Chester disease and juvenile xanthogranuloma.[90]

Some neuroblastomas can also express full-length ALK protein, but in contrast to ALCL, the staining is weak.[166] Somatic and germline mutations of the *ALK* kinase domain have been reported in familial neuroblastoma.[167] ALK expression is well-known in a subset of non–small cell lung cancers associated with the transforming *EML4-ALK* fusion gene,[168,169] but also more recently reported in melanocytic tumors,[170] epithelioid fibrous histiocytomas,[171] and rare soft tissue myxoid tumors.[172]

Primary Cutaneous CD30-Positive T-Cell Lymphoproliferative Disorders

Skin involvement by systemic ALCL can cause diagnostic confusion with primary cutaneous CD30-positive T-cell lymphoproliferative disorders (see **Chapter 39**). Three types of primary cutaneous CD30-positive T-cell lymphoproliferative disorders are distinguished[9]: primary cutaneous ALCL, lymphomatoid papulosis (in which type C shows the most resemblance to ALCL), and borderline lesions. The distinction among these disorders is sometimes difficult and requires the combined assessment of histologic, clinical, and phenotypic features. The expression of EMA is variable. Although ALK protein usually is absent in these

lymphoproliferative disorders, rare cases of primary cutaneous ALK-positive ALCL have been reported.[173-175]

ALK-Negative Anaplastic Large Cell Lymphomas Associated With Breast Implants

The diagnosis of BIA-ALCL must be restricted to patients with this distinct clinical context. Secondary breast involvement by a systemic ALK-negative ALCL must be excluded. Breast involvement by PTCL, NOS with a population of CD30-positive large cells may also be responsible for diagnostic difficulties. Some cases reported as ALK-negative BIA-ALCL seem to correspond to the latter entity. In fact, the most difficult differential diagnosis is to rule out the diagnosis of CHL in some cases of BIA-ALCL with RS-like cells, in a background rich in eosinophils. Diagnostic difficulties may be accentuated by the positive staining for CD15 as seen in rare cases of BIA-ALCL (personal observation).[137] However, the clinical context (i.e., breast implant), the rarity (if it exists) of primary breast CHL, and the phenotype of atypical cells (CD30 positive, EMA positive/negative, T phenotype, and PAX5 negative) allow exclusion of CHL.[123]

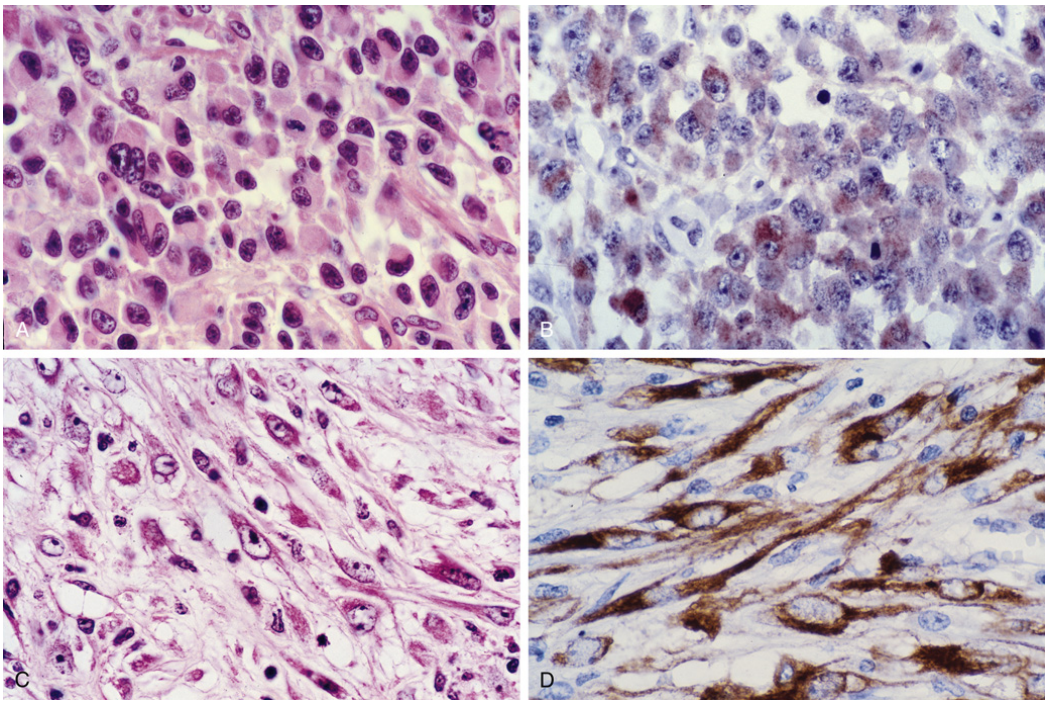

FIGURE 36-14 Rare soft tissue tumors may express anaplastic lymphoma kinase (ALK) but are negative for CD30 antigen. **A–B,** Rhabdomyosarcoma positive for full-length ALK protein (**A,** hematoxylin and eosin [H&E]; **B,** ALK staining). This tumor was strongly positive for desmin. **C–D,** Inflammatory myofibroblastic tumor strongly positive for ALK protein (**C,** H&E; **D,** ALK staining). Usually this tumor expresses TPM4-ALK protein.

Pearls and Pitfalls

- Beware that anaplastic large cell lymphoma (ALCL), anaplastic lymphoma kinase (ALK) postive exhibits a broad spectrum of

morphologic features. Do not hesitate to ask for ALK staining.

- Classic Hodgkin lymphoma (CHL) rich in neoplastic cells may be misdiagnosed as ALK-negative ALCL based on negative CD15 staining. Remember that 15% to 25% of CHLs are negative for CD15. CHL also may express T-cell antigens. Additional staining using CD20 and CD79a (which are positive on a proportion of Reed-Sternberg [RS] cells in 30% of cases), PAX5, and Epstein-Barr virus (EBV)–encoded RNA (EBER) in situ hybridization may be useful. ALK-negative ALCL is always negative for EBV.
- In addition to CHL, strong CD30 staining may be observed in peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS); in some extranodal T-cell lymphomas, such as extranodal NK/T-cell lymphoma, nasal type, and enteropathy-associated T-cell lymphoma; in mast cell proliferations; in some diffuse large B-cell lymphomas; and in some nonlymphoid malignancies, such as embryonal carcinoma, melanoma, and some undifferentiated carcinomas.

Intestinal T-Cell Lymphoma, Not Otherwise Specified

INDOLENT NATURAL KILLER–CELL AND T-CELL LYMPHOPROLIFERATIVE DISORDERS OF THE GASTROINTESTINAL TRACT

Indolent Natural Killer–Cell Lymphoproliferative Disorder of the Gastrointestinal Tract

Indolent Clonal T-Cell Lymphoproliferative Disorder of the Gastrointestinal Tract

Enteropathy-Associated T-Cell Lymphoma

An association between malabsorption and intestinal lymphoma was first reported in 1937,[1] at which time lymphoma was considered responsible for the malabsorption. However, in 1962, Gough and coworkers[2] demonstrated that intestinal lymphoma was a complication of celiac disease or gluten-sensitive enteropathy. In 1978, Isaacson and Wright[3] characterized celiac disease–associated lymphoma as a single entity, originally considered a form of malignant histiocytosis. Later, Isaacson and coworkers[4] showed that the neoplastic cells were of T-cell lineage. This lymphoma subtype was categorized in the 2008 World Health Organization (WHO) classification as enteropathy-associated T-cell lymphoma (EATL) type I,[5] or classic EATL. In the revised WHO 4th ed. classification, it was designated simply as *EATL*.[6,7] The 2022 International

Consensus classification (ICC)[8] retains the terminology of the revised WHO 4th ed. classification,[6,7] as does the WHO 5th ed. classification.[9]

Definition

EATL is a neoplasm derived from intraepithelial lymphocytes (IELs) showing variable degrees of cellular pleomorphism, often within a polymorphic background.

Synonyms and Related Terms

WHO revised 4th ed., 2017: Enteropathy-associated T-cell lymphoma[7]
WHO 5th ed., 2022: Enteropathy-associated T-cell lymphoma[9]

Epidemiology

EATL is the most common subtype of primary intestinal T-cell lymphoma (66%–80%).[10,11] However, it is a rare lymphoma, accounting for less than 1% of non-Hodgkin lymphomas, less than 5% of primary gastrointestinal lymphomas, and approximately 5% of peripheral T-cell lymphomas (PTCLs) in Western countries.[11,12] EATL characteristically occurs in the 6th and 7th decades of life, although it has been reported in younger adults.[11,13-16] A male predominance (1.04–2.8:1) has been observed in most series.[11,13-16] Most, if not all, patients with EATL have the celiac disease–associated *HLADQA1*0501, DQB1*0201* (HLA-DQ2) genotype.[17] EATL is more common in regions with a high seroprevalence of celiac disease, such as Europe (EATL incidence of 0.05–

0.14/100,000)[14,15,18] and the United States (EATL incidence of 0.016/100,000).[19] The reasons for a higher incidence of EATL in individuals of northern European descent (and in certain European countries) despite a similar incidence of celiac disease in most Western countries are unknown. EATL is virtually nonexistent in regions such as the Far East, where most lack the celiac disease susceptibility alleles. There is an increased incidence of EATL in older individuals, 2.92/100,000 in the 60-to-69-year-old age group and 0.05/100,000 in people older than 60 years in Europe and the United States, respectively.[15,19] The incidence of EATL in the celiac population is 0.22 to 1.9/100,000.[20-23] A wide range in the relative risk of non-Hodgkin lymphoma, including EATL, has been reported for celiac disease (and dermatitis herpetiformis) patients (3–100), with population-based studies providing more reliable estimates (at the lower end of the range).[20,24-28]

Etiology

EATL is a recognized complication of celiac disease,[29,30] a common autoimmune disorder (incidence, 1% in most regions of the world) with myriad intestinal and extraintestinal manifestations that occurs in genetically susceptible individuals intolerant to gluten-containing grains (e.g., wheat, barley, and rye).[31] In retrospective studies of patients with EATL, celiac disease has been diagnosed in 38% to 100% of affected patients; this variation is likely a result of incomplete data or inclusion of non-EATL cases.[11,13-16] Evidence for an association between celiac disease and EATL comes from identical human leukocyte antigen (HLA) types in celiac disease patients and those with EATL,[17] the demonstration of gluten

sensitivity in EATL patients,[29] and the protective effect of a gluten-free diet against the development of lymphoma[21,24,32]; the risk of lymphoma decreases, albeit gradually, after commencing a gluten-free diet.[26] Homozygosity for HLA-DQ2 alleles, observed in 53% of cases (compared with 21% in uncomplicated celiac disease), is considered a risk factor for development of EATL.[33]

A diagnosis of celiac disease is established in 20% to 73% of cases before the diagnosis of EATL.[13,14,16,34] A short history of "adult-onset" celiac disease usually predates EATL, but it may occur in individuals with long-standing disease, the mean time between diagnosis of celiac disease and EATL ranging from 46.8 months to 10 years.[10,13,24,35] In 10% to 58% of cases, celiac disease and EATL are diagnosed simultaneously, with up to one-third being discovered at surgery for intestinal obstruction or perforation,[13,14,16,36] and the diagnosis of celiac disease is occasionally made at autopsy.[13,14] At times, EATL might occur in patients only manifesting celiac-associated extraintestinal conditions, such as dermatitis herpetiformis.[20,27,28] Gastrointestinal symptoms in celiac disease do not correlate with the degree of small intestinal mucosal damage,[37] and more than 50% of patients may be asymptomatic.[38] Hence, certain individuals with EATL might have had lifelong "silent" or "cryptic" gluten sensitivity because villous atrophy and crypt hyperplasia are found in uninvolved small intestinal mucosa when the tumor is resected. The only manifestation of celiac disease in some cases is an increase in IELs, and in a minority, the jejunum appears nearly normal. Studies showing that the jejunal mucosa can appear normal in "latent" celiac disease[39] might provide an

explanation for this finding, which was previously thought to argue against a strict association between EATL and celiac disease.

Clinical Presentation

EATL most commonly presents with abdominal pain (65%–100%) and development of gluten-insensitive malabsorption or diarrhea (40%–70%) in previously well individuals or those with a history of adult-onset (or childhood-onset) celiac disease and a prior response to a gluten-free diet. Other presentations include weight loss (50%–80%), acute abdominal emergency due to intestinal perforation (25%–50%), hemorrhage, anorexia, fatigue, and early satiety or vomiting caused by intestinal obstruction.[11,13,14,16,34,36,40,41] Ichthyotic rash and finger clubbing may be observed. B symptoms, besides weight loss, are present in less than one-third of patients.[16,34,36] The duration of symptoms can range from 1 week to 5 years,[16] and a symptom duration of less than 3 months before EATL diagnosis was observed in 59% of cases in one study.[14]

Small intestinal involvement is detected in 90% to 96% of de novo EATLs,[11,13,14] most commonly in the jejunum.[16] The frequency of small intestinal involvement by EATL with prior refractory celiac disease type II (RCD II) is lower (65%).[13] Multifocal lesions involving different segments of small intestine are seen in 32% to 54%, ulcers or strictures in 51%, and mass lesions in 32% of cases.[13,16] The next most common gastrointestinal sites are the large intestine and stomach.[11] EATL might occasionally present at extraintestinal locations (e.g., skin, lymph nodes, spleen, or central nervous system),[11,13,42,43] usually in cases evolving from RCD II, as the aberrant IELs in RCD II frequently disseminate to extraintestinal

sites (**Table 37-1**).[13,44,45] Common sites of EATL dissemination include intraabdominal lymph nodes (35%), bone marrow (3%–18%), lung and mediastinal lymph nodes (5%–16%), liver (2%–8%), and skin (5%).[11,13,14] Advanced disease at diagnosis has been reported in 43% to 90% of cases, although the staging systems used in different studies have varied.[11,13,14,16] An Eastern Cooperative Oncology Group (ECOG) score >1 is noted in 88%, and many patients have a poor performance status.[14,16] Elevated lactate dehydrogenase levels are observed in 25% to 62%, low serum albumin concentrations in 76% to 88%, and low hemoglobin levels in 54% to 91% of patients.[11,13,14,16] Abnormalities of the white blood cell count, renal function tests, and erythrocyte sedimentation rate, as well as elevated C-reactive protein and alkaline phosphatase levels, are detected in more than one-third of patients.[11,14,16] A hemophagocytic syndrome may occur in 16% to 40% of cases.[13,46]

Table 37-1

cyt, Cytoplasmic; *EATL,* enteropathy-associated T-cell lymphoma; *IEL,* intraepithelial lymphocyte; *s,* surface; *TR,* T-cell receptor gene.

Pathology

Macroscopic Appearance

The tumor may form ulcerating nodules, plaques, strictures, or, less commonly, large masses (**Fig. 37-1**). The adjacent mucosa might appear thin and show loss of mucosal folds. The mesentery is frequently infiltrated, and mesenteric lymph nodes are commonly involved. There is sometimes remarkably little macroscopic evidence of disease in the intestine as opposed to the mesenteric lymph nodes.

Histopathology

The histologic features of EATL show great variation both between cases and within a single case (**Fig. 37-2**). Generally, a transmural, polymorphic cellular infiltrate is observed, composed of numerous inflammatory cells, particularly eosinophils and plasma cells, which may obscure the scattered or small clusters of pleomorphic, intermediate-to-large-sized neoplastic lymphocytes (**Fig. 37-2**). Large cells with anaplastic features are seen in 40% of cases.[13] In some cases, the tumor cells can be monomorphic and display prominent central nucleoli (immunoblastic appearance). Angiocentricity and angioinvasion leading to blood vessel destruction is not uncommon, and foci of necrosis are present in a large proportion of cases. Increased numbers of histiocytes are often seen admixed with the neoplastic cells, and granulomas may be present, causing confusion with Crohn's disease. Increased mucosal and submucosal vascularity can occasionally be a prominent feature. Intraepithelial spread of tumor cells may be striking, though in some cases, only rare atypical lymphocytes are observed within the epithelium (**Fig. 37-3**).

FIGURE 37-1 Resected jejunum from a patient with enteropathy-associated T-cell lymphoma shows multiple ulcerating tumors.

The histology of the small intestinal mucosa remote from the tumor is an important consideration in the diagnosis of EATL. In most cases, the changes are identical to those of celiac disease, consisting of villous atrophy and crypt hyperplasia, lymphoplasmacytic infiltrates in the lamina propria, and increased IELs (**Fig. 37-4**). As in uncomplicated celiac disease, the mucosal changes are maximal proximally and improve distally hence the lower jejunum and ileum may be normal. In some cases, the mucosal changes can be subtle.

Numerous shallow ulcers extending into the submucosa are often present remote from the lymphoma. The ulcer bases show granulation tissue and infiltrates of small lymphocytes and plasma

cells, and a virtual absence of neoplastic cells (**Fig. 37-5**). Episodes of ulceration followed by healing lead to scarring with stricture formation and distortion of the mucosal architecture, accompanied by destruction of the muscularis mucosa and the emergence of glands lined by cells of the ulceration-associated cell lineage,[47] previously called *pseudopyloric metaplasia* (**Fig. 37-6**).

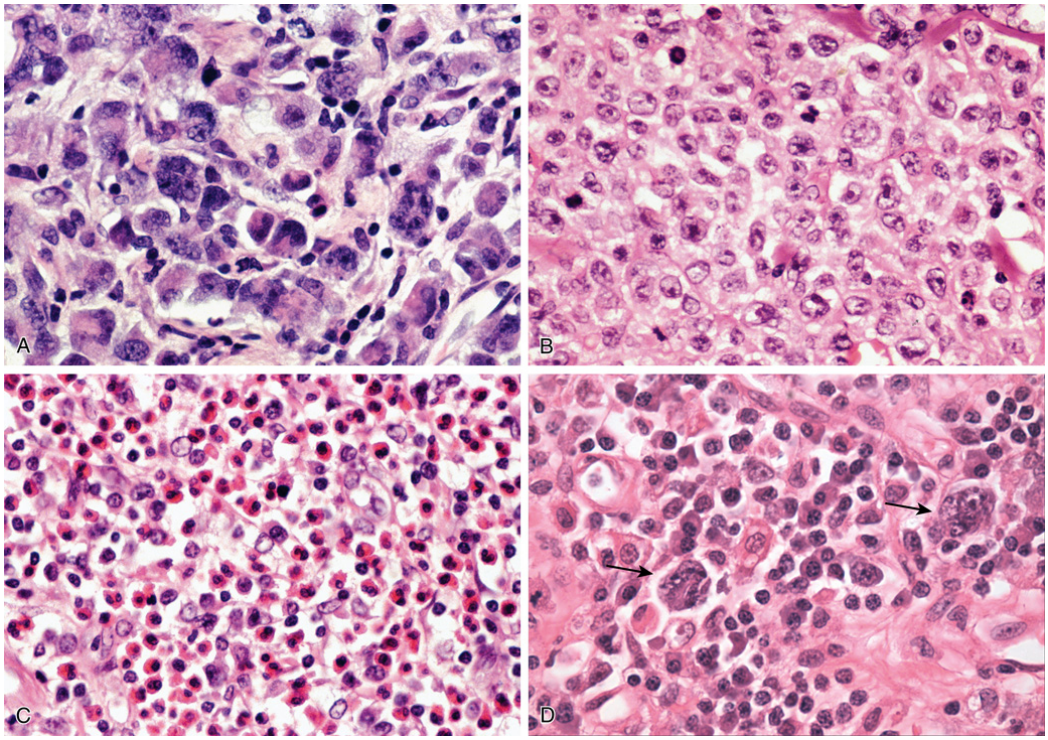

FIGURE 37-2 Histologic appearance of enteropathy-associated T-cell lymphoma.A, Typical case composed of pleomorphic large cells. **B,** In this case, the tumor cells are immunoblastic. **C,** Heavy inflammatory infiltrate containing principally eosinophils almost obscures the tumor cells. **D,** Scattered large multinucleated tumor cells in a plasma cell–rich inflammatory infiltrate.

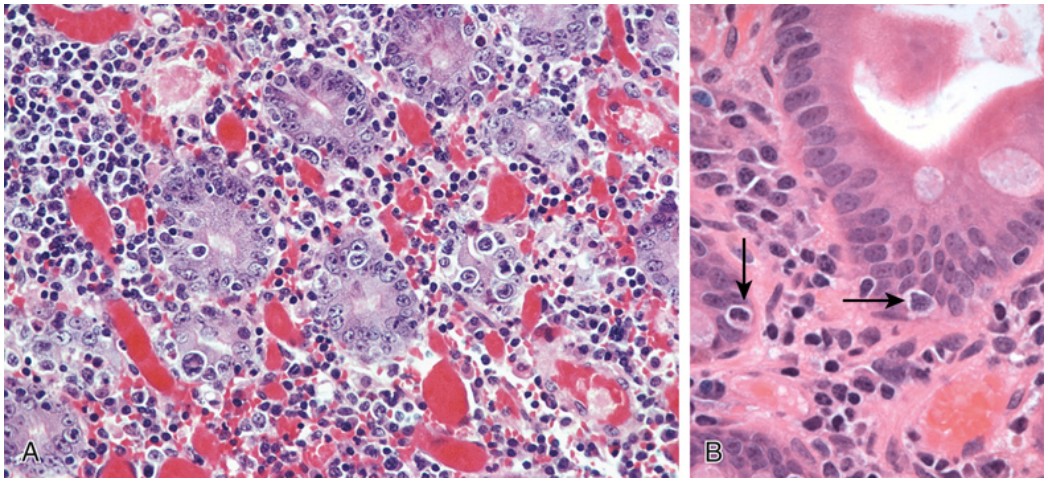

FIGURE 37-3 Intraepithelial spread of enteropathy-associated T-cell lymphoma in the small intestinal mucosa.A, Numerous large intraepithelial neoplastic cells are seen in the epithelium overlying an invasive tumor. **B,** Rare, large, atypical intraepithelial lymphocytes are seen in a duodenal biopsy specimen lacking obvious lymphoma.

Lymph Node Involvement

The pattern of mesenteric (or other) lymph node involvement may be predominantly intrasinusoidal or paracortical, or both compartments may be involved (**Fig. 37-7**). Lymph nodes remote from the EATL can show varying degrees of necrosis in the absence of a morphologically recognizable neoplastic cellular infiltrate (**Fig. 37-8**). Abdominal (and extraabdominal) lymph nodes may show a spectrum of changes ranging from lymphocyte depletion and fibrosis to dissolution of the node and replacement with lymph fluid (**Fig. 37-8**), referred to as *lymph node cavitation*.[48,49] At times, these

lymph nodes can undergo calcification. Similar lymph node alterations can also be observed in individuals with long-standing untreated celiac disease or RCD, often accompanied by splenic atrophy.[49-51] Lymphatic and blood vessel damage by the neoplastic (or non-neoplastic) cytotoxic IELs trafficking to the lymph nodes and bystander killing of nodal constituents possibly contribute to lymph node destruction.

Immunohistochemistry

In most cases of EATL, the neoplastic lymphocytes express CD103, CD3 (cytoplasmic), CD7, T-cell intracellular antigen-1 (TIA-1), perforin, and granzyme B. They are usually negative for CD5, CD4, CD8, and CD56, and similar to RCD II, the majority lack surface and cytoplasmic T-cell receptor (TR) expression (**Fig. 37-9**). However, these immunophenotypic features are not constant, and the phenotypic profiles of synchronous and metachronous tumors can differ. Cytoplasmic TRβ chain (βF1) expression can been detected in up to 25% of EATLs.[10,52,53] Some cases may show TRγ chain (or surface TRγδ) expression (**Fig. 37-10**) and dual TR expression (lineage infidelity) is rarely observed.[54-57] CD8 expression has been described in 19% to 30% of EATLs overall,[10,13,52,53] with a higher frequency (50%) reported in cases not associated with RCD II.[13] In occasional cases, the neoplastic cells fail to express CD3, perforin, or CD103.[13,45,58] CD30 expression varies in the different cytomorphologic variants, but almost all EATLs manifesting large cell morphology are CD30 positive (see **Fig. 37-9**).[13] Although some tumors resemble anaplastic large cell lymphoma (ALCL), EATLs are anaplastic lymphoma kinase negative except in very rare instances.[59]

EATLs are Epstein-Barr virus (EBV)–negative lymphomas, but admixed EBV-positive lymphocytes may be present. Virtually all cases display elevated Ki67 proliferation indices (>50%). Immunohistochemistry is useful in detecting single scattered neoplastic cells in cases lacking a mass lesion and also for discerning increased IELs, as evidence of celiac disease, when small intestinal mucosal architecture in the vicinity of EATLs appears normal (**Fig. 37-11**). The immunophenotype of IELs in the uninvolved small intestinal mucosa is normal in de novo EATLs, but they exhibit an aberrant phenotype in cases preceded by RCD II (see later; see also **Table 37-1**).

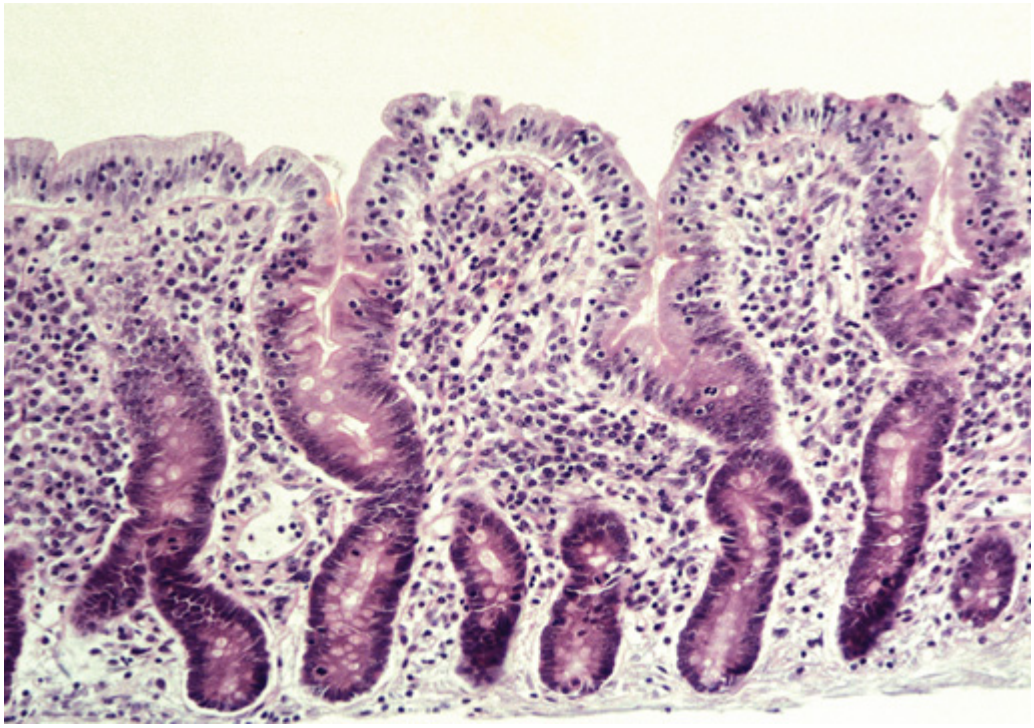

FIGURE 37-4 Small intestinal mucosa remote from enteropathy-associated T-cell lymphoma shows villous atrophy, crypt hyperplasia, and increased intraepithelial lymphocytes.

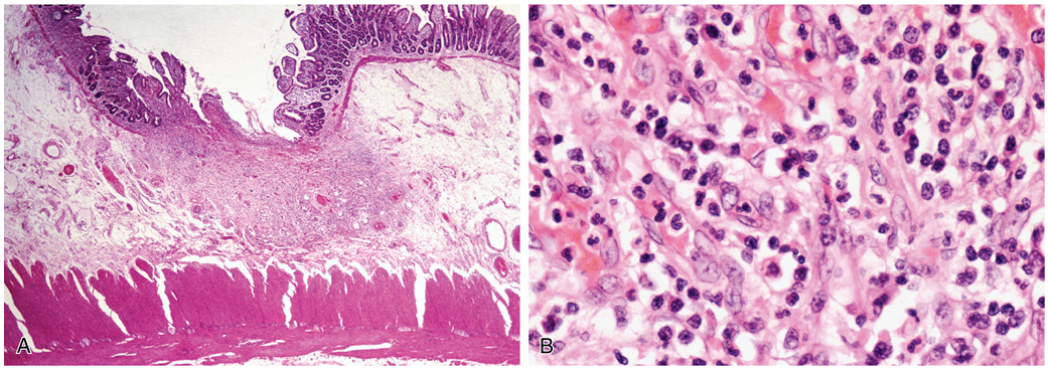

FIGURE 37-5 **A,** Shallow mucosal ulcer in a case of enteropathy-associated T-cell lymphoma. Similar changes can also be seen in cases of ulcerative jejunitis. **B,** High magnification of the ulcer base shows granulation tissue and no evidence of lymphoma.

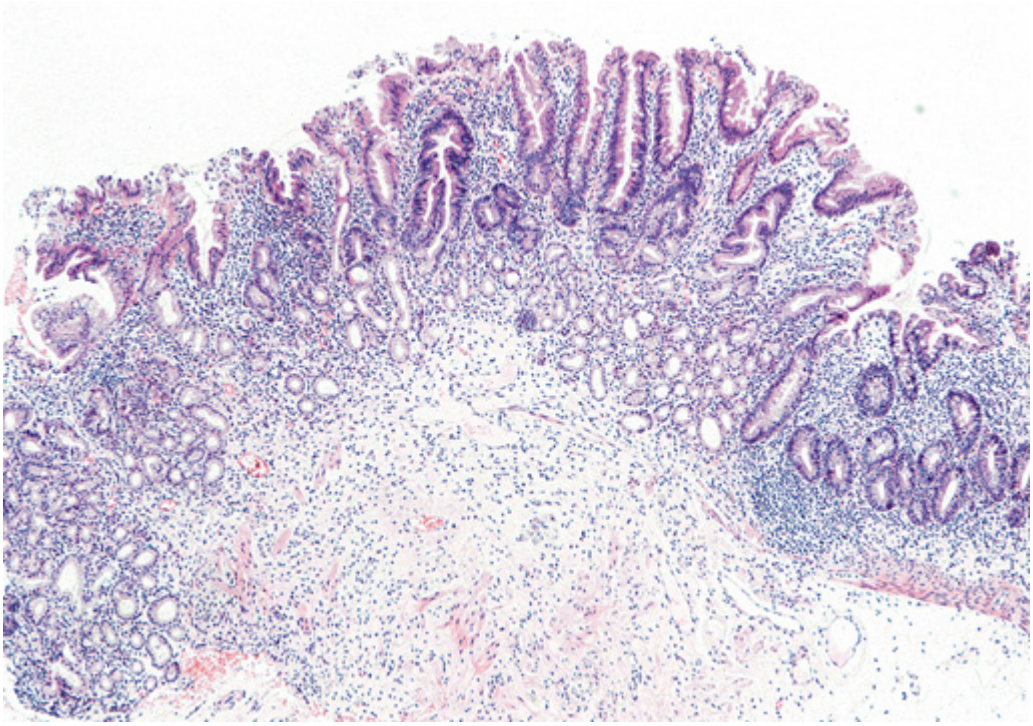

FIGURE 37-6 Healed ulcer in the nonlymphomatous small intestinal mucosa in a case of enteropathy-associated T-cell lymphoma. There is destruction of the muscularis mucosa, fibrosis of the mucosa and submucosa, and ulceration-associated cell lineage metaplasia of the intestinal crypts.

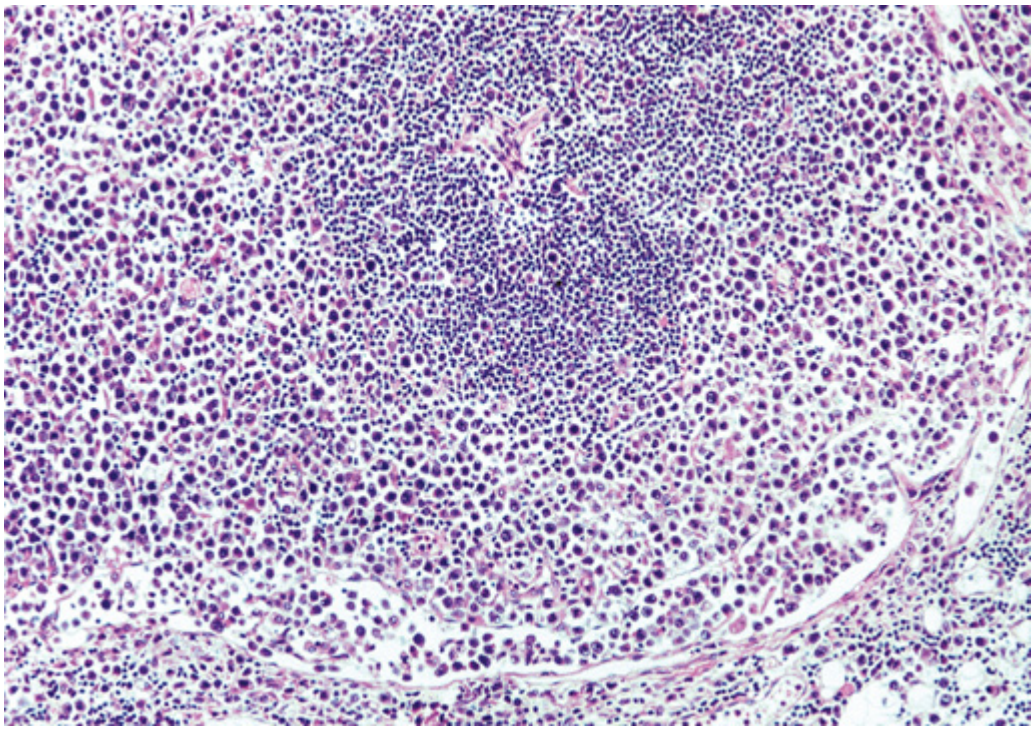

FIGURE 37-7 Dissemination of enteropathy-associated T-cell lymphoma to a mesenteric lymph node.

Clinical Course

The clinical course of EATL is unfavorable, with median survival ranging from 5 to 10 months and 1-year and 5-year overall survival of 31% to 38.7% and 0% to 58.8%, respectively.[13,14,16,34,36,41,60] Prognostic factors are not well established for this entity. However, the recently developed EATL prognostic index (EPI) has shown better outcome prediction than the International Prognostic Index (IPI) and the prognostic index for PTCL (PIT).[61] Malnutrition, which is common in EATL patients with prior RCD II, is considered responsible for their markedly lower 5-year survival (0%–8%) compared with those with de novo EATL (58.8%).[13,60] Surgical

resection is impractical in many cases because of involvement of multiple intestinal segments and dissemination of disease beyond the mesenteric lymph nodes. Although remissions are nondurable, patients receiving chemotherapy with or without surgical resection have higher overall (40%–58%) and complete (27%–43%) response rates and longer survival than those treated with surgery alone.[13,41,62] Better outcomes have been reported for patients treated with intensive chemotherapy followed by autologous stem cell transplantation (4-year and 5-year overall and progression-free survival of 71% and 60% and 71% and 52%, respectively).[14,63] Death is usually attributed to EATL, malnutrition, infections, or complications of therapy.[13,14]

Pathogenesis

Postulated Cell of Origin

EATL is derived from IELs on the basis of shared immunophenotypic features, including integrin $\alpha_E\beta_7$ (HML-1, CD103) expression.[13,64] IELs comprise a phenotypically heterogeneous population of thymus-derived T-cells and bone marrow-derived innate lymphoid cells (ILCs).[65-73] De novo EATLs are thought to arise from the neoplastic transformation of intraepithelial T-cells that have

undergone TRA and B rearrangement, express TRαβ and the CD8αβ heterodimer (CD8αβ), and exhibit major histocompatibility complex class I restriction. These lymphocytes, which are referred to as conventional, type a, or induced IELs, account for 80% of all human small intestinal IELs.[74,75] They have latent cytotoxic potential (TIA-1 positive, perforin negative, granzyme B negative)[76,77] and migrate to the intestine in response to antigen stimulation.[78] T-cells that have rearranged TRG and D but not TRB (γδ T-cells) account for up to 15% of IELs, and the majority display a "double negative" (CD4 and CD8 negative) phenotype.[68,79] The immunophenotypic profile of some EATLs suggests derivation from γδ T-cells; however, the frequency of such cases is presently unknown.[53-57] Since RCD II has been proposed to develop from ILCs, a similar cell of origin is speculated for EATLs evolving from RCD II.

Molecular Analysis and Genetic Abnormalities

Polymerase chain reaction (PCR) analysis for TRB or TRG rearrangement yields clonal TR rearrangements in virtually all EATLs.[13,52,80]

Segmental amplifications of the chromosome 9q31.3-qter region encompassing known proto-oncogenes (e.g., *NOTCH1, ABL1, VAV2*) or, alternatively, deletions at 16q12.1 have been reported in >80% of EATLs, and a small subset lacking 9q34 amplification exhibits allelic imbalances at 3q27.[81-85] Other common recurrent changes include gains at 1q, 5q, and 7q and losses at 8p, 9p, and 13q, with some studies suggesting gains at 1q and 5q to be more frequent in EATL than in other primary intestinal T-cell lymphomas (**Table 37-2**).[13,81,84] Although losses involving the 9p21 locus are detected in

10% to 13% of EATLs, loss of heterozygosity (LOH) at 9p21, targeting the cell cycle inhibitors *CDKN2A/B,* has been observed in up to 56% of cases, with consequent loss of p16 protein expression.[58,81,82] Loss or LOH of the 17p12-p13.2 region, harboring the *TP53* tumor suppressor gene, is noted in 20% and 31% of cases, respectively, but aberrant nuclear p53 expression can be seen in 75% of cases, indicating additional mechanisms of *TP53* deregulation.[58,81,84] EATLs display a significantly higher mean frequency of microsatellite instability, albeit low-level overall, compared with monomorphic epitheliotropic intestinal T-cell lymphomas (MEITLs).[84]

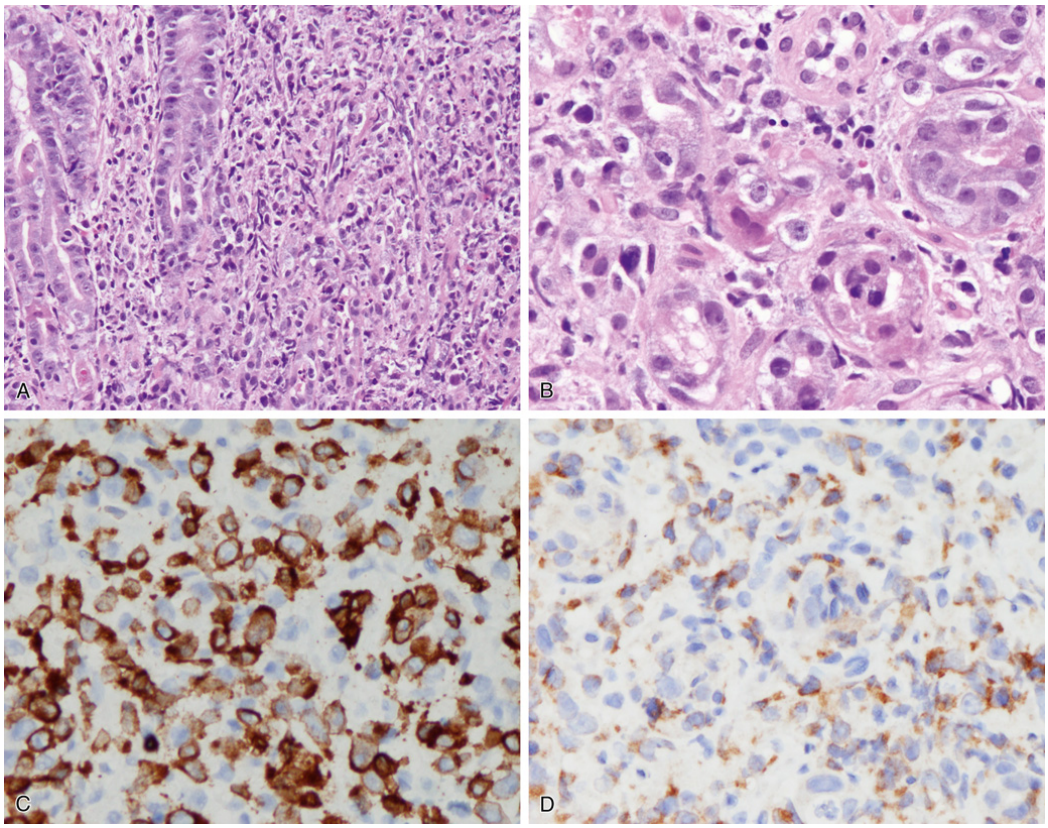

FIGURE 37-10 Enteropathy-associated T-cell lymphoma involving stomach.A, Neoplastic lymphocytes have destroyed gastric glands. **B,** Large atypical lymphocytes are seen infiltrating glandular epithelium. **C,** Immunohistochemistry for CD3 highlights the pleomorphic large lymphocytic infiltrate. **D,** Immunohistochemistry for TRγ shows weak expression in a subset of neoplastic cells. Flow cytometry showed no CD8 or surface CD3 and TR expression, and polymerase chain reaction (PCR) analysis detected a clonal TRB rearrangement.

ALK and *DUSP22* rearrangements, characteristic of ALK-positive and ALK-negative ALCLs, have been reported in rare cases of

EATL,[59,86,87] with one study documenting secondary acquisition of *DUSP22* rearrangement.[87]

The mutational profiles of de novo and RCD II-associated EATLs overlap with RCD II, but the variant allele frequencies (VAFs) of the somatic alterations are higher in most EATLs and these tumors show emergence of new driver mutations.[88] JAK-STAT pathway mutations are the most pervasive (50%–100%),[85,88-90] commonly involving *JAK1* (20%–74%) and *STAT3* (20%–47%), the vast majority representing activating *JAK1* JH1 kinase and *STAT3* SH2 domain mutations. Multiple *JAK1* or *STAT3* mutations occur in 21% and *JAK1/STAT3* double mutations in approximately one-third of EATLs,[88] while mutations in *JAK3* (0%–10%) and *STAT5B* (0%–10%) are infrequent.[85,88-90] Recurrent mutations are also observed in epigenetic regulators (up to 74%), including *KMT2D* (37%) and *TET2* (15%–32%), members of the NF-κB signaling pathway (33%) including *TNFAIP3* (28%) and *TNIP3* (6%), and DNA damage response and repair pathway (32%) including *POT1* (26%) and *TP53* (5%–10%), and in *DDX3X* (32%), *PRDM1/BLIMP1* (12%–17%), and *BCOR* (16%).[85] *SETD2* mutations (or deletions) are uncommon and RAS-MAPK pathway mutations (≈20%) appear less frequent than in MEITL.[85,88-90] In a limited number of cases evaluated, the mean number and spectrum of mutations detected by targeted sequencing were comparable between de novo and RCD II-associated EATLs.[90] However, *JAK1* mutations, observed in all de novo EATLs, were only seen in 50% of RCD II-associated EATLs, and mutations in *TNFAIP3* were restricted to the latter.

FIGURE 37-11 **A,** Enteropathy-associated T-cell lymphoma with overlying mucosa displaying well-formed villi. **B,** Higher magnification of villi immunostained with CD3 shows increased numbers of intraepithelial lymphocytes.

Transcriptome sequencing has shown higher expression of *IRF1/4, STAT3/5A,* and *TGM2* (autoantigen in celiac disease) genes in EATL compared to MEITL, and gene set enrichment analysis has disclosed significant overexpression of the interferon (IFN) γ pathway in EATL, which is a key signaling cascade in celiac disease IELs.[85]

Refractory Celiac Disease

Some individuals with celiac disease may become unresponsive to a gluten-free diet after a variable time or be nonresponsive de novo, a

condition associated with heightened morbidity and mortality, referred to as refractory sprue or refractory celiac disease (RCD).[91]

Between 1989 and 2001, a number of investigators demonstrated unique pathologic features of a fraction of adult-onset RCD cases and uncovered an association between such cases and a related disorder, ulcerative jejunitis (see **Fig. 37-5**),[92] and EATL.[40,52,80,93-96] Although the histologic features of intact mucosa were indistinguishable from untreated celiac disease, the IELs in certain RCD cases displayed an aberrant immunophenotype (see later; see also **Table 37-1**). TR rearrangement analysis, performed on biopsy specimens or purified IELs, detected clonal products in a high proportion of these cases, and identical clones were observed in ulcerated and intact mucosa and samples of co-existent or subsequent EATLs.[40,52,80,93,95-97] These findings led to the belief that a subset of RCD cases represent low-grade lymphomas of intraepithelial T lymphocytes or cryptic EATL.[94,95,98]

Definition and Classification

RCD is defined as persistent gastrointestinal symptoms and abnormal small intestinal mucosal architecture with increased IELs, despite a strict gluten-free diet for >12 months.[99] The diagnosis of RCD requires exclusion of certain celiac disease–related conditions (e.g., pancreatic insufficiency, bacterial overgrowth, microscopic colitis, lymphoma) and other small intestinal disorders (e.g., common variable immune deficiency, autoimmune enteropathy, drug-related injury) as causes of the symptoms. RCD may be *primary,* if there is no response to a gluten-free diet at diagnosis, or *secondary,* if refractoriness to gluten-free diet develops after an

initial response. Clinicopathologic studies have shown RCD to encompass heterogeneous disorders.[45,60,100,101]

Currently, RCD is categorized into two types based on immunophenotypic and molecular criteria (see **Table 37-1**): type I, if the IEL phenotype is normal (i.e., they express surface CD3, CD8, and TR) and polyclonal products are detected on TR rearrangement analysis; and type II, if the IEL immunophenotype is aberrant (i.e., surface CD3, CD8, and TR expression is absent) and a clonal T-cell population is identified by TR rearrangement analysis.[99] Although of practical utility, this dichotomous classification has limitations (e.g., lack of consensus for cutoff values for the percentage of abnormal IELs and criteria to define clonality), and it does not capture the full spectrum of RCD II (e.g., surface CD8-positive or CD3-positive/TR-positive cases). The 2022 ICC recognizes RCD II as a precursor lesion to EATL,[8] because 30% to 50% of cases transform to overt EATL within 5 years.[102]

Synonyms and Related Terms

The 2022 ICC recognizes RCDII as a precursor lesion to EATL.

Epidemiology

The true prevalence of RCD and its subtypes is not known as most studies have been conducted at specialized centers and diagnostic criteria have varied. Studies from the United States and Europe report a wide range in the prevalence of RCD (1.5%–10%) in celiac disease patients.[100,101,103-105] Ulcerative jejunitis, which can be a manifestation of RCD II, was documented in 0.7% of celiac patients in the United Kingdom.[106] An epidemiologic survey from Finland,

however, indicates that RCD is a rare complication of celiac disease, with a point prevalence of 0.31% in celiac patients and 0.002% in the general population.[51] Most studies describe a higher frequency of RCD I (68%–80% of all RCD cases),[45,51,60,100,101,107] and although a higher proportion of women are diagnosed with RCD I and II (69%–78% and 58%–60% of all cases, respectively), the frequency of men with RCD II is higher than in uncomplicated celiac disease.

Table 37-2

Pathologic and Genetic Features of Enteropathy-Associated T-Cell Lymphoma and Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma

	EATL	MEITL
Frequency	66%–80%	20%–34%
Morphology	Variable, usually pleomorphic cells	Usually monomorphic small-to-medium-sized cells
Immunophenotype		
CD8	Negative (19%–30% positive)	Positive (10%–31% negative)
CD56	Negative	Positive (3%–25% negative)
HLA-DQ2/DQ8	90% positive	30%–40% positive
Chromosome/DNA copy number variants		
+9q31.3 or −16q12.1	86%	83%
+1q32.2-q41	73%	27%

	EATL	MEITL
+5q34-q35.2	80%	20%
+8q24 *(MYC)*	27%	13%–73%
Mutations		
JAK/STAT pathway	50%–100% *(JAK1>JAK3, STAT3>STAT5B)*	75%–89% *(JAK3>JAK1, STAT5B>STAT3)*
Epigenetic regulators	74% (*SETD2* rare)	33%–100% (*SETD2* >90%)
NF-κB pathway	33%	Unknown
RAS-MAP kinase pathway	20%	30%–53%
DNA damage response/repair pathway	32%	33%–44%
DDX3X	32%	3%
GNAI2	Unknown	9%–24%

EATL, Enteropathy-associated T-cell lymphoma; *MEITL,* monomorphic epitheliotropic intestinal T-cell lymphoma.

Etiology

Similar to EATL, the duration and dose of gluten exposure appear to be risk factors for RCD, as homozygosity for HLA-DQ2 is observed in

44% to 67% of RCD II and 25% to 40% of RCD I cases,[33,45] and the majority of RCD patients are older than 50 years.[45,51,100] Environmental factors, specifically infections, have been suggested to increase susceptibility to RCD, but conclusive evidence is lacking at present.[45,108,109] The possibility of non-HLA genetic variants predisposing to RCD also exists. A genome-wide association study has reported significant association of a single nucleotide polymorphism on chromosome 7p14.3 with progression of celiac disease to RCD II.[110]

Clinical Presentation

Secondary refractoriness to a gluten-free diet is more common in individuals with RCD I (70%) compared to those with RCD II (50%),[45] while the latter have a higher frequency (and severity) of symptoms (60%–70% versus 30% in RCD I).[45,51,100] RCD II patients are severely malnourished (body mass index <18), with up to 90% presenting with protein-losing enteropathy or low serum albumin levels.[45,51,100] Large mucosal ulcers (>1 cm) are often seen on endoscopy in RCD II but not in RCD I patients.[45] Because the aberrant IELs often disseminate to other gastrointestinal organs (46%–64% of cases) and extragastrointestinal sites (60% of cases), including peripheral blood (44%–51% of cases), RCD II patients may present with extraintestinal symptoms or disorders (e.g., skin lesions; see **Table 37-1**).[44,45,111]

Histopathology

Small intestinal histologic features of RCD I or II are similar to those observed in untreated celiac disease (Figs. **37-12** and **37-13**). At

diagnosis, a high proportion of both subtypes manifest severe degrees of villous atrophy (subtotal or total); rare cases of RCD II may only exhibit crypt hyperplasia.[112] Intraepithelial lymphocytosis is evident, but the IELs lack significant cytologic atypia. At times, IELs extend deep within the crypts in RCD II (**Fig. 37-13**),[113] in contrast to uncomplicated celiac disease and RCD I, where they are mostly confined to the superficial regions of the villous-crypt unit. Although difficult to discern in RCD II, mild patchy lymphocytosis or small aggregates of lymphocytes might be seen in the lamina propria (representing IEL infiltrates), especially adjacent crypts (**Fig. 37-13**). Moreover, aberrant IELs can be widely distributed throughout the gastrointestinal tract, from the stomach to the anus.[40,44,45] Hence, one needs to recognize that EATLs evolving from prior RCD II may arise at sites besides the small intestine.

Mucosal ulceration associated with granulation tissue and variable degrees of chronic inflammation (ulcerative jejunitis; see **Fig. 37-5**),[40,45,60,80,93] is more frequently noted in RCD II, and presence of collagenous sprue or collagenous celiac disease has been reported in a subset of RCD I cases.[96,114]

Immunophenotypic and Molecular Analysis

In cases of suspected RCD, the IEL phenotype is best assessed by multiparametric flow cytometry of small intestinal biopsy specimens, as this modality is more sensitive than immunohistochemistry, allows simultaneous interrogation of multiple antigens, and can distinguish between surface (s) and cytoplasmic (cyt) antigen expression. Similar to uncomplicated celiac disease, more than 90%

of IELs in RCD express CD103 (HML-1) or $\alpha_E\beta_7$ integrin, which is a receptor for E-cadherin.[115,116]

In RCD I, the majority of IELs are thymus-derived T-cells that express sCD3, sCD8, and sTRαβ (see **Fig. 37-12** and **Table 37-1**).[117] The intensity of CD5 is variable, similar to normal small intestinal intraepithelial T-cells.[118] Upregulation of certain activating natural killer (NK)-cell receptors (e.g., CD94/NKG2C) can be observed,[45] and intraepithelial TRγδ-positive T-cells are normally elevated.[119]

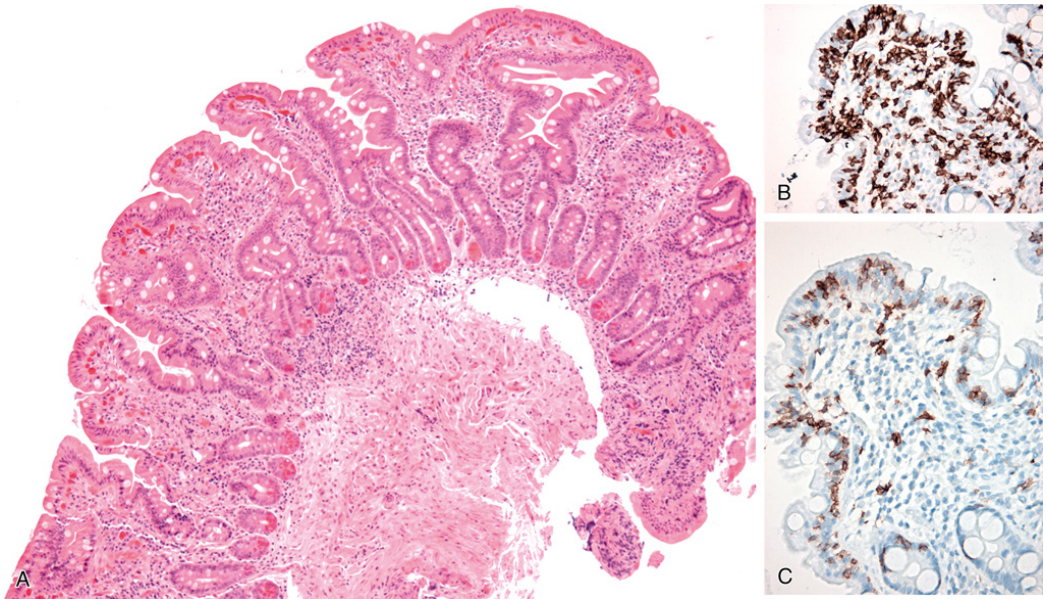

FIGURE 37-12 Refractory celiac disease type I.A, The small intestinal mucosa shows partial villous atrophy, crypt hyperplasia, and increased intraepithelial lymphocytes. **B,** The intraepithelial lymphocytes express CD3. **C,** Most intraepithelial lymphocytes also express CD8.

In classical cases of RCD II, an increased proportion of IELs (>20% to virtually 100%) are sCD3 negative and sTR negative, but

they express intracellular CD3ε. The IELs generally show bright CD7 expression and are CD5 negative, and CD2 expression can vary.[113,117] CD8 expression is usually absent (see **Fig. 37-13** and **Table 37-1**).[40,93] However, cases of RCD II with variant phenotypes, including CD8-positive cases, have been documented in multiple studies.[45,54,113,120-122] The IELs in some RCD II cases display cytTRβ (βF1) expression,[95,96,120,121,123] and rarely may express sCD3 and sTRαβ or sTRγδ, or lack cytCD3 expression.[88,113] Most cases exhibit a spectrum of activating NK-cell receptors (e.g., NKG2D, NKp46),[97,124,125] and a threshold of >25 NKp46-positive IELs per 100 epithelial cells can reliably discriminate RCD II from RCD I.[126] In contrast to EATLs, IELs in RCD II have low proliferation indices, as assessed by Ki67 or proliferating cell nuclear antigen staining.[109,113,118] Presence of CD30-positive IELs should alert one to the possibility of unsampled EATL, as IELs in RCD II do not express CD30.[120] Although aberrant lymphocytes represent a major proportion of IELs, they may account for >20% of lamina propria lymphoid cells in up to 50% of RCD II cases.[111,113]

Immunohistochemical staining of small intestinal biopsy specimens has been used for the evaluation of aberrant IELs and classification of RCD. Most studies have used a cutoff of <50% CD8-positive IELs in formalin-fixed, paraffin embedded biopsy specimens to classify cases as RCD II.[40,44,100,101] Although it is practical, rapid, and cost-effective, immunohistochemistry has limitations and pitfalls. A high interobserver variability and low sensitivity in detecting cases with low frequencies of aberrant IELs have been reported for this method.[127] Substantial expansions of TRγδ-positive IELs that are mostly CD8 negative are not uncommon in biopsy

specimens of celiac disease (and RCD I) patients, which in the absence of TRγ staining may be misinterpreted as “phenotypically aberrant” IELs.[96] Furthermore, CD8-positive RCD II cases will be missed by this approach. Discrepancies in the reported frequencies and clinical outcomes of RCD II patients might relate to the use of different modalities for disease classification. Diagnosis of RCD II by flow cytometry can also be challenging at times because of the presence of other IEL subsets, especially ILCs,[128] which manifest a phenotype similar to aberrant IELs (CD103+, sCD3−, cytCD3ε+, CD5−, CD8−), but these cells typically do not exceed 20% of IELs.[68,70,71]

Clonality assessment is important, yet by itself is inadequate for RCD categorization, as analytical and biological factors can give rise to discordant results. PCR analysis for TRB or G rearrangement generally yields polyclonal products in RCD I (**Fig. 37-14**; see also **Table 37-1**) and clonal products in RCD II (**Fig. 37-15C**; see also **Table 37-1**).[13,40,45,52,95,96,100,105,122] However, clonal TR rearrangements can occasionally be observed in RCD I,[129] and they may be absent in up to one-third of RCD II cases.[118,129,130] Furthermore, CDR3 sequencing of RCD II cases with clonal rearrangements has revealed incomplete or nonfunctional TRG, D, and B rearrangements in ≈70% of cases.[130] Nonetheless, PCR-based assessment of TR rearrangement is useful in establishing a clonal relationship between RCD II and concomitant or subsequent EATLs (**Fig. 37-15C**).[13,80,95,96,122]

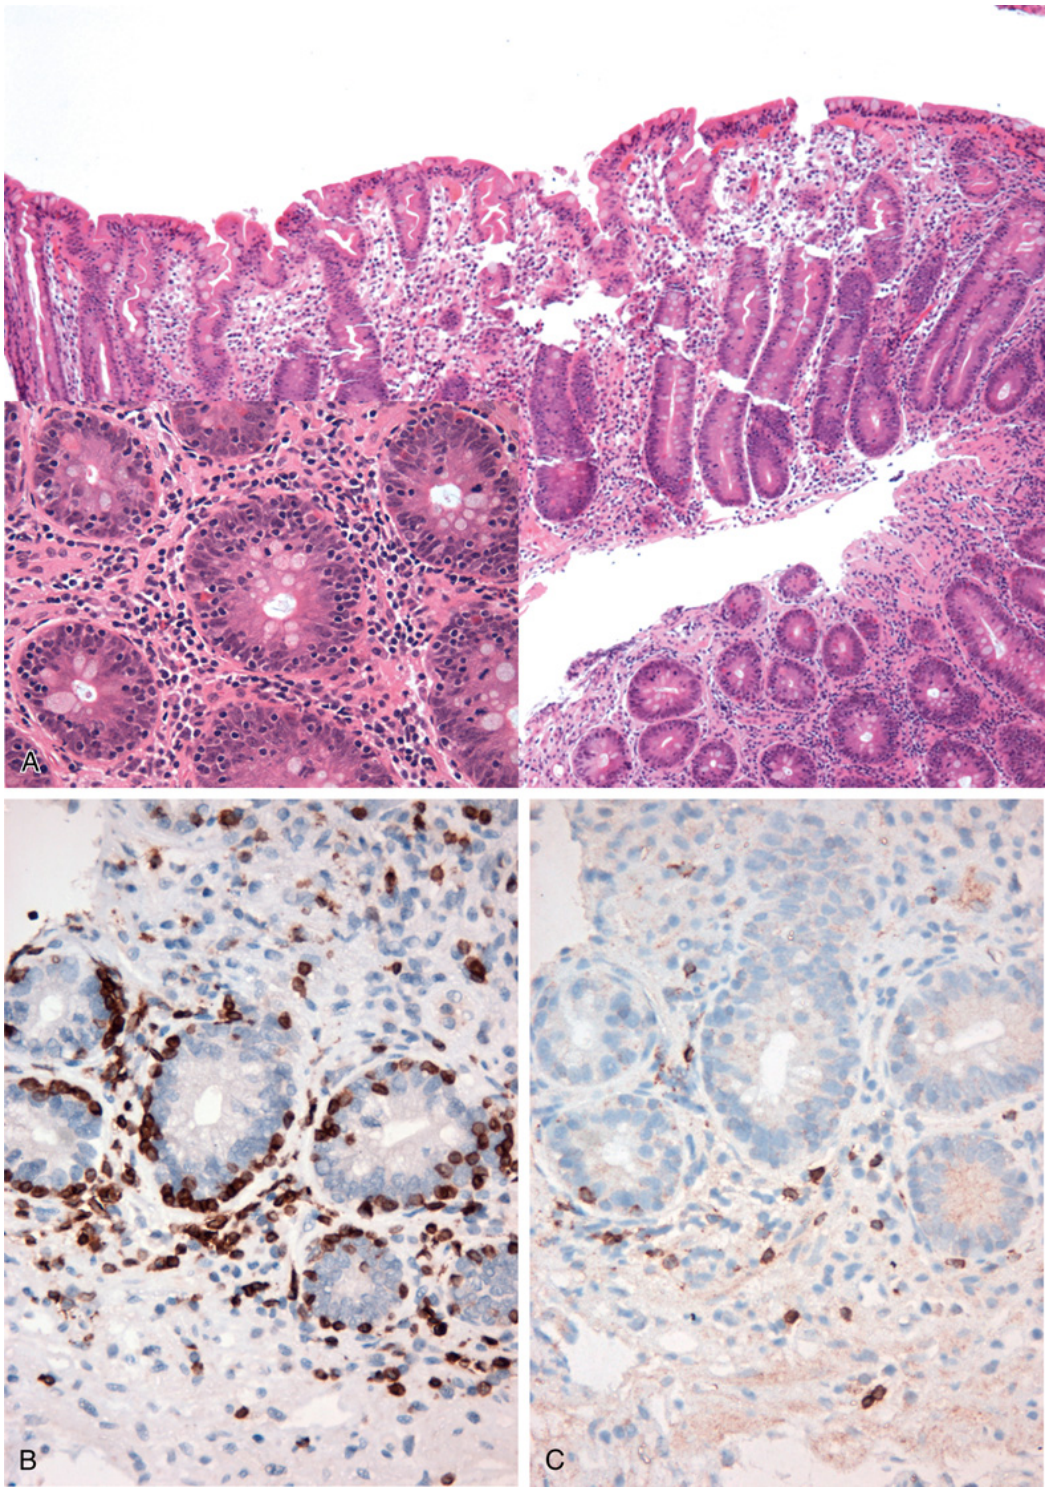

FIGURE 37-13 Refractory celiac disease type II.A, The small intestinal mucosa shows total villous atrophy, crypt hyperplasia, and

increased intraepithelial lymphocytes (*inset:* extension of the lymphocytes into crypt epithelium). **B,** The intraepithelial lymphocytes express CD3 (note small clusters of CD3-positive lymphocytes in lamina propria–adjacent crypts). **C,** Virtually all intraepithelial lymphocytes and most pericryptal, lamina propria lymphocytes are CD8 negative.

Immunophenotypic, genomic, and transcriptional analyses of RCD II cell lines and IELs, as well as functional studies, have suggested an IL-15 responsive subset of bone marrow derived ILCs residing in the small intestinal epithelium to be the normal counterpart of aberrant IELs.[125,130,131] Under physiologic conditions, these cells can differentiate into T-cells and NK-cells, but inactivation of NOTCH1 signaling by IL-15 limits T-cell development in RCD II. The differentiation level of the aberrant IELs varies among cases. An advanced maturation stage of RCD II IELs and a higher intensity of cytCD3 expression (relative to expression of normal IELs) have been associated with an increased risk of progression to EATL.[132,133] Because of the phenotypic heterogeneity of RCD II, an origin of some cases from other subsets of IELs cannot be ruled out.

Clinical Course

The 5-year survival of RCD II patients (44%–58%) is markedly inferior to that of RCD I patients (80%–96%), which is attributed to more severe malnutrition and a higher risk for development of EATL (30%–52% in 4–6 years for RCD II versus 3%–14% for RCD I; see **Table 37-1**).[45,51,60,100] RCD I patients in whom surreptitious gluten

ingestion has been excluded benefit from immunomodulatory drug (glucocorticoids, azathioprine, and enteric-coated budesonide) therapy.[99,134] Treatment of RCD II patients is challenging. Clinical and pathologic improvement has been documented with open capsule budesonide, which is the preferred first-line therapy.[135] Chemotherapy (e.g., cladribine, alkylating agents) with or without autologous stem cell transplantation, is unable to eradicate the neoplastic cells.[99,136] An improvement in symptoms was reported with use of an anti-IL-15 monoclonal antibody without a significant reduction in aberrant IELs.[137] In vitro studies have demonstrated antiproliferative and cytocidal effects of JAK1-STAT3 pathway inhibitors,[88] but their clinical efficacy remains to be determined.

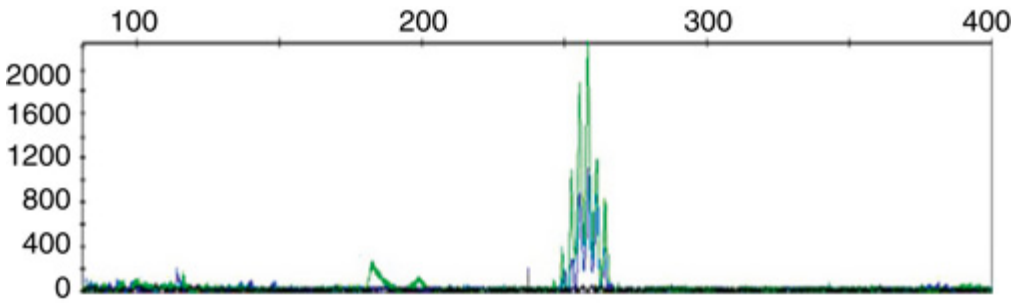

FIGURE 37-14 Fluorescent polymerase chain reaction (PCR) analysis for TRB rearrangement and capillary gel electrophoresis performed on a small intestinal biopsy sample from a patient with refractory celiac disease type I shows polyclonal products.

Pathogenesis

The pathogenesis of RCD I is unclear but appears to be multifactorial. Inadvertent, low-level gluten ingestion is considered responsible for sustaining intestinal inflammation in at least one-third of patients,[105,138] and transition from a gluten-driven to an autoimmune response is suspected in some cases.[109] No genetic alterations have yet been identified in this subtype.[88] RCD II is a prototypic inflammation-associated lymphoproliferative disorder. Epithelial stress induced by cytotoxic gliadin peptides results in upregulation of IL-15, which augments IFN-γ production and cytotoxicity of aberrant IELs resulting in epithelial damage, and synergizes with cytokines secreted by gliadin-responsive CD4-positive T cells in the lamina propria (e.g., IL-2, TNF-α, IL-21) to stimulate proliferation and enhance the survival of IELs by activating the JAK-STAT signaling cascade.[109,124,139-143]

and capillary gel electrophoresis show gastric spread and transformation of one of the two duodenal neoplastic T-cell clones.

Somatic mutations have been detected in 80% to 90% of RCD II cases, with mutations in JAK-STAT pathway genes constituting the most frequent alterations (up to 86% of cases) observed in cases displaying classical as well as variant immunophenotypes.[88,113] *JAK1* (36%–48%) and *STAT3* (38%–64%) are the commonly targeted genes. Loss of function mutations in negative regulators of the pathway *(SOCS1, SOCS3, SH2B3)* also occur, albeit at lower frequencies. Other recurrently mutated gene classes and pathways comprise epigenetic regulators (64%), including *TET2* (30%–45%) and *KMT2D* (22%–45%); NF-κB signaling (22%–27%), including *TNFAIP3/A20* (13%–27%) and *TNIP3* (9%); immune escape (20%–36%), including *CD58* (12%–18%) and *FAS* (6%–9%), and DNA damage response/repair (27%), including *POT1* (≈20%) and *TP53* (4%). Mutations in the X-linked RNA helicase *DDX3X* and *BCOR* are seen in 20% and 10% of cases, respectively. The aberrant IELs in virtually all RCD II cases express phospho-STAT3 by immunohistochemistry,[113] and JAK1-STAT3 and NF-κB pathway mutations have been shown to constitutively activate signaling or enhance responsiveness of the IELs to IL-15 and TNF-α, respectively.[88,130] Mutations in *JAK1,* especially the *JAK1* p.G1097 hotspot mutation are present in about half the cases, and *STAT3* and *TNFAIP3* are maintained in RCD II–associated EATL, suggesting driver roles of these alterations.[88,113]

Recurrent trisomies of chromosome 1q22-q44 have been identified on cytogenetic analysis of RCD II cell lines and biopsies.[45,144] Array-

based analyses have confirmed 1q gains and also revealed frequent losses at 4q and 6q, including *TNIP3* and *TNFAIP3/A20* loci, respectively.[88,113] Loss of p16 protein, in the absence of LOH at chromosome 9p21, has been reported in 40% of ulcerative jejunitis cases, and aberrant nuclear p53 expression has been detected in 57% of cases in the absence of molecular lesions of *TP53*.[58] Altogether, these observations indicate dysregulated JAK1-STAT3 and NF-κB signaling, disruptions of epigenetic and cell cycle regulators and tumor suppressors, and chromosome 1q gains to be early events in the genesis of RCD II-associated EATL.

Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma

Before the era of immunophenotyping, it was assumed that rare primary intestinal lymphomas composed of uniform, small, round lymphocytes represented cytomorphologic variants of EATL, as they were associated with villous atrophy and intraepithelial lymphocytosis of the uninvolved mucosa. In 1992 Chott and colleagues[145] suggested the existence of at least one subtype of primary intestinal PTCL exhibiting similar architectural and infiltration patterns as EATL but lacking enteropathy. The immunophenotype of the tumor cells of this aggressive variant (CD3 positive, CD8 positive, CD56 positive) was subsequently shown to be different from NK-cell lymphomas and most cases of EATL.[10] Although it shared some clinical features and genetic properties with EATL, there were distinct differences.[10,81] This type of intestinal T-cell lymphoma was categorized as EATL type II in the 2008 WHO 4th ed. classification.[5] Subsequently, studies from Asia confirmed

the lack of association between this entity and celiac disease,[146-148] and it was renamed *CD56-positive monomorphic intestinal T-cell lymphoma* in the 2010 4th ed. WHO classification of tumors of the digestive system.[149] Recognition of the not-infrequent variability in phenotype of this neoplasm, especially with regard to CD8 and CD56 expression, as well as its lineage,[55,150-160] led to the designation *monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL)* in the revised WHO 4th ed. classification,[6,7] a term that is maintained in the 2022 ICC and WHO 5th ed. classification.[8,9]

Definition

MEITL is a neoplasm derived from IELs, with most cases characterized by small-to-medium-sized lymphocytes, usually exhibiting minimal cellular pleomorphism.

Synonyms and Related Terms

WHO revised 4th ed., 2017: Monomorphic epitheliotropic intestinal T-cell lymphoma[6,7]

WHO 5th ed., 2022: Monomorphic epitheliotropic intestinal T-cell lymphoma[9]

Epidemiology

MEITL has a wider geographic distribution than EATL, representing up to 34% of primary intestinal T-cell lymphomas in Europe and the United States[10,11] and the majority of primary intestinal T-cell lymphomas in Asia.[150,151,152] Like EATL, it is a rare neoplasm, representing ≈4% of primary intestinal lymphomas in Asia and <5% of Western and 1.9% of Asian PTCL cases.[11,153] It usually occurs in

the 5th and 6th decades of life; however, similar to EATL, MEITL has been documented in younger individuals.[55,150-156] Males are affected more frequently than females (male-to-female ratio, 1.8–2.6:1).[55,150,151] The true incidence and prevalence of MEITL is not known at present.

Etiology

The etiology of MEITL is unknown. Although a clinical history of celiac disease or "histologic enteropathy" has been reported in a variable proportion of cases,[10,11,55,150-154] the frequency of HLA-DQ2/DQ8 alleles in Western cases mirrors that of the normal population (30%–40%),[81,85,139] and series of well-characterized cases from Europe and Asia have reported a lack of association with celiac disease i.e., absence of steatorrhea or malabsorption[10,55,150,151,155,156] and negative celiac serology (anti–tissue transglutaminase and anti–endomysial antibodies).[10,151] The occurrence of isolated large intestinal disease in some individuals also supports distinct etiopathogenesis.[150,151,156-158] Expansions of IELs with an aberrant phenotype are not uncommon in the uninvolved small intestinal mucosa of patients with MEITL. However, a prior indolent precursor phase, analogous to RCD II, has not been established in this entity.

Clinical Presentation

An acute presentation has been reported in 40% to 85% of cases. Common symptoms and signs include abdominal pain (31%–89%), perforation (12%–70%), weight loss (28%–63%), diarrhea (21%–45%), obstruction (16%–28%), and bleeding (4%–17%).[10,55,85,150-

[158] B symptoms are noted in 36% to 48% of patients.[85,150,153,156] The small intestine is the most common primary site of lymphoma (73%–95%),[55,150,151,156,85,155] with jejunal and ileal involvement noted in 50% to 73% and 27% to 45% of cases, respectively.[10,151,156] Concurrent stomach and large bowel disease is detected in 5% and 5% to 28% of cases, respectively,[55,150-152,158] and multifocal disease is observed in 12% to 58% of cases, most often involving the jejunum and ileum.[10,55,150,154,153,156] Individuals with small intestine involvement, with or without large intestine involvement, have more advanced disease, whereas those with isolated large intestinal involvement (10%–18%) seem to have more localized disease.[150,151] Sites of disease dissemination include abdominal or inguinal lymph nodes (27%–44%), omentum or mesentery (22%), abdominal or pelvic organs (5%–11%), lung/pleura (5%–12%), bone marrow (3%–12%), and cervical lymph nodes (6%), and central nervous system involvement may be observed on occasion.[55,105,151,153,155,156] The extent of disease at diagnosis varies between studies, with high-stage disease (Lugano IIE-IV) reported in 33% to 73% of cases.[150-156] The frequency of patients with good performance status (ECOG ≤1) ranges from 43% to 76%, lactate dehydrogenase levels are elevated in 29% to 91%, and analogous to EATL, a high proportion of individuals have hypoalbuminemia (67%–90%).[150,153-156]

Pathology

Macroscopic Appearance

Similar to EATL, MEITL can present as solitary or multiple tumors, which may show central ulceration, at times with exudate. In some instances, the overlying mucosa might appear nodular. Strictures are

less common. Mucosal folds adjacent to tumors are often enlarged or swollen, and the muscularis propria is often thin and stretched. Gross involvement of mesenteric and abdominal lymph nodes is not uncommon.

Histopathology

In the majority of cases, the neoplastic lymphocytes are small-to-medium-sized and have small nuclei with fine granular chromatin, inconspicuous or small nucleoli, and scant to moderate pale pink or clear cytoplasm (monocytoid appearance). There is usually little variation in cell size within a given tumor. A variable proportion of cases, however, can be comprised of large lymphocytes with irregular nuclei, vesicular chromatin, and prominent nucleoli, or exhibit significant cellular pleomorphism.[10,151,152,155,157] A subset of cases may also manifest other atypical morphologic features such as a starry-sky appearance or increased apoptotic activity, angiocentricity or angioinvasion, and coagulative necrosis.[155,157] In contrast to EATLs, chronic inflammatory cells are either absent or sparse in nearly all MEITLs.[55,151,155] Most lymphomas have a central "tumor zone" characterized by a dense and diffuse transmural infiltrate of neoplastic cells and frequent ulceration and perforation (**Fig. 37-16**); a "peripheral zone" representing lateral, predominantly mucosal infiltration by lymphoma associated with crypt destruction and variable degrees of villous atrophy, which in 68% to 89% of cases displays prominent epitheliotropism by the atypical lymphocytes (**Fig. 37-17**); and a contiguous or distant "IEL zone" (35%–100% of cases) exhibiting normal villous architecture or mild villous atrophy

and increased IELs lacking cytologic atypia (small size and hyperchromatic nuclei).[10,55,150-155,157]

Immunohistochemistry

MEITLs exhibit a distinctive cytotoxic immunophenotype in that the tumor cells express CD3, CD8, CD56 (see **Fig. 37-16**), and TIA-1, but similar to EATL, most express CD7 and >90% lack CD5 expression (**Table 37-3**). A minority may express CD4 (3%–11%) or both CD4 and CD8 (3%–19%).[53,150,152,155,158] Of the CD8-positive cases, 77% have been shown to express CD8α homodimers (CD8αα), and the remainder, CD8αβ heterodimers.[151] Studies have highlighted variability in the expression of T-cell antigens by a proportion (or all) of the neoplastic lymphocytes at diagnosis or relapse.[53,55,150-155,157,158,161] Notably, absence of CD8 and CD56 has been described in 10% to 31% and 3% to 25% of cases, respectively (up to 11% lacking both), and 2% to 18% can be TIA-1 negative; granzyme B and perforin expression is heterogeneous and positivity is lower than TIA-1.[55,150-158] Lack of βF1 expression has been reported in 54% to 90% of cases,[10,53,150,151,155,157,161,162] and TRγ or TRδ expression has been documented in 26% to 78% of tumors, indicating TRγδ lineage[55,150,151,155,157]; some of these may lack surface TR expression by flow cytometry but show cytoplasmic TRγ expression (**Fig. 37-18**). A variable number of cases (6%–34%) are "TR silent," lacking both βF1 and TRγ/δ expression,[53,55,150,151,154,155,157] whereas co-expression of TRβ and TRγ/δ (lineage infidelity) is observed in 3% to 17% of cases.[53,55,151,155,157] A high proportion of cases (91%) express phospho-MEK1/2, evidence of mitogen-activated protein kinase

(MAPK) pathway activation.[154] Megakaryocyte-associated tyrosine kinase (MATK) and spleen tyrosine kinase (SYK), expressed by 87% and 95% of cases, respectively, are highly discriminatory for MEITL, as they are not expressed by EATL.[53,151] Aberrant expression of B-cell antigens, usually by a subset of the neoplastic cells and weaker in intensity than normal B-cells, has been recorded in 10% to 24% of cases.[55,151,155,158] Positivity for CD20 is more common than CD79a and occasional tumors can co-express both antigens, but PAX5 is negative. Both CD103-positive and CD103-negative MEITLs exist, the former accounting for 80% of cases in a large series.[155] Epithelial membrane antigen is usually negative and CD30 expression is only noted in rare instances.[6,53,152,155,156] A few studies have reported EBV infection in a minority of cases (≈10%); it is not certain if some (or all) such cases represent primary intestinal extranodal NK/T-cell lymphomas, nasal type.[10,150,162] The Ki67 labeling index of the tumor cells is >50% in the majority of cases.[53,55,155] C-MYC overexpression and aberrant P53 expression have both been described in 30% to 40% of MEITLs overall, and in a greater proportion of cases exhibiting atypical morphology.[154,155]

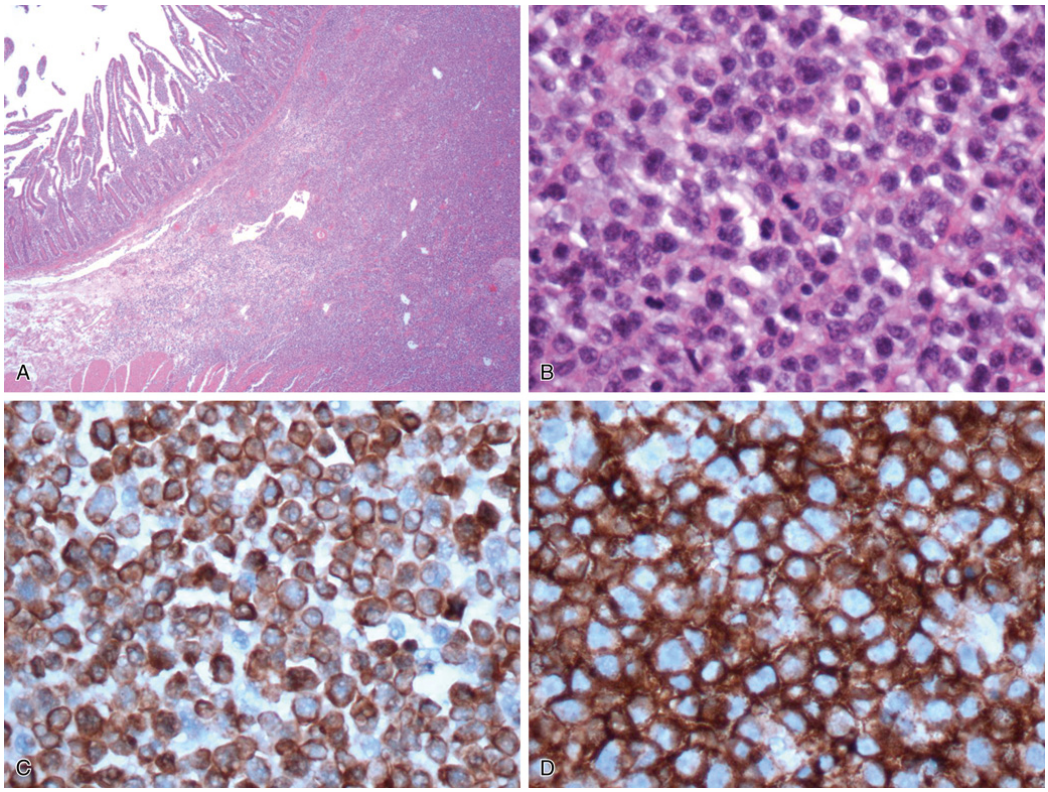

FIGURE 37-16 **A,** Monomorphic epitheliotropic intestinal T-cell lymphoma showing transmural infiltration by neoplastic lymphocytes ("tumor zone"). **B,** The neoplastic cells are medium sized. **C,** The majority are CD8 positive. **D,** Most show intense CD56 expression.

The immunophenotype of the atypical IELs in the peripheral zone is similar to the tumor in the central zone (see **Fig. 37-17**) or intermediate between that of the tumor and the mature appearing IELs in the distal mucosa.[55,151] The antigen profile of the latter has been shown to be discordant with the tumor in up to 65% of cases (CD56 and MATK expression is usually weak or negative in IELs, while CD2, CD8, and TR are expressed by the IELs, but may be downregulated/absent in the tumor).[55,147,151] In contrast to the

mucosal infiltrate, the Ki67 proliferation index of the intraepithelial component is low (<10%).[55]

Clinical Course

Similar to EATLs, the clinical outcome of patients with MEITL is poor, with median survival ranging from 7 to 14.8 months.[85,150,151,154-156,158] One-year and 5-year overall survival rates of 31% to 57% and 32%, respectively, have been reported.[55,85,150,154-156] Prognostic factors are not well established for this disease. A recent study described independent adverse prognostic effects of *TP53* and *STAT5B* mutations and a favorable prognosis for cases expressing B-cell antigens.[155] Response to initial therapy is associated with better overall and progression-free survival, and a good performance status (≤1) is associated with better overall survival.[150,155,156] The use of chemotherapy is associated with higher response rates compared with surgery alone. The overall and complete response rate of patients receiving chemotherapy, with or without surgical resection, is 44% to 59% and 16% to 43%, respectively.[150,151,155,156] Limited data regarding autologous bone marrow transplantation after intensive chemotherapy appear promising, with 4-year and 5-year overall survival rates of 45% and 28%.[55,63,150,151,156]

Pathogenesis

Postulated Cell of Origin

MEITL is considered to arise from either intraepithelial TRαβ or TRγδ T-cells, the majority expressing CD8α homodimers (CD8αα) irrespective of αβ or γδ lineage.[151] The ontogeny of CD8αα-positive TRαβ-positive and CD8αα-positive TRγδ-positive IELs, also referred to as unconventional, type b, or natural IELs, has not been clarified in humans.[74,75] The thymus appears to be the major source of natural IELs in mice. Extrathymic development of a subset of natural IELs, especially TRγδ T-cells, has been suggested,[163] but this remains controversial. Under certain conditions, expression of CD8αα (and CD103) can also be acquired by conventional CD8αβ T-cells ("induced" CD8αα IELs).[164,165] The development or maintenance of CD8ααT-cell subsets is dependent on a variety of transcription factors (TBET, RUNX3, and MYC) and cytokines (IL-15, IL-27, and transforming growth factor β1).[166-169]

Because of the nearly ubiquitous expression of CD56, derivation from an intestinal CD56-positive IEL subset has been speculated for MEITL. In humans, small intestinal CD3-positive CD56-positive lymphocytes comprise a minor but heterogeneous population, including NK-T cells and invariant NK-T cells, accounting for approximately 10% of all IELs overall.[66,69,71,170,171] However, CD56 can be induced in diverse T-cells upon activation.[172,173] This knowledge, the intertumoral and intratumoral variability in CD56 expression, and CD56 negativity of IELs at a distance from the tumor in a significant proportion of cases, argue against an origin of MEITLs from a specific CD56-positive IEL subset.[55,147,151,155] It is currently believed that intraepithelial CD8-positive T-cells with

latent cytotoxic potential upregulate CD56, MATK, and cytotoxic granule proteins upon neoplastic transformation or disease progression.[151] Whether specific infectious, immune, or dietary factors lead to the preferential activation or expansion of select innate IELs and play a role in the initiation of MEITLs remains to be determined.

Molecular Analysis and Genetic Abnormalities

Clonal TR rearrangements are detected in 91% to 95% of MEITLs,[150,151,162] and a clonal relationship between the tumor and distant IELs lacking atypia has been established in the limited number of cases analyzed.[147,151,160]

Genomic changes in MEITLs are similar to those in EATLs (see **Fig. 37-18** and **Table 37-2**), but the frequencies of some aberrations vary.[81,85,90,157,158,174,175] The prevalence of chromosome 9q and 7q gains and losses at 8p and 16q is comparable to that observed in EATL, while gains at 1q and 5q appear less frequent in this disease. In contrast to EATL, losses at 3p21.31/*SETD2* locus (27%–33% of cases) and gains at 8q, encompassing 8q24/*CMYC* locus (13%–73% of cases), are more common in MEITL (**Table 37-2**),[81,85,90,151,154,155,157,158,161,174] and *CMYC* translocations are seen in 4% to 7% of cases.[151,155]

The functional gene classes and pathways mutated in MEITL also overlap with EATL; however, some differences are apparent. Genetic alterations of epigenetic regulators are among the most frequent events in MEITL (33%–100)[85,89,90,152,155,158,174,175a] with *SETD2* inactivation by mutation or deletion being a unique feature of this disease, including cases with atypical morphology and

immunophenotype, and irrespective of the TR status. *SETD2* alterations have been documented in >90% of lymphomas in many, but not all, series (range 22%–100%) and multiple *SETD2* aberrations have been detected in 33% to 75% of cases. Additional mutated genes include *CREBBP* (11%–30%), *TET2* (6%–15%), and *KMT2D* (6%). *SETD2,* which encodes a histone H3 lysine methyltransferase, orchestrates diverse processes, including DNA damage signaling and repair, chromosome segregation, transcriptional regulation and mRNA processing, and functions as a tumor suppressor.[176] Loss of SETD2 protein expression and decreased/absent H3K36 trimethylation is seen in 70% to 90% and 83% to 95% of cases with *SETD2* alterations, respectively,[90,155,175a] and H3K36me3 immunohistochemistry has been shown to be a reliable method for inferring *SETD2* abnormalities.[155]

JAK-STAT pathway mutations are observed in 75% to 89% of tumors.[85,89,90,152,155,158,174,175a] As opposed to EATL, mutations in *JAK3* (33%–67%) and *STAT5B* (33%–65%) are more common in MEITL, most representing activating JH2 pseudokinase and SH2 domain mutations, respectively, while *JAK1* (2%–44%) and *STAT3* (0%–11%) mutations are less prevalent. Multiple *JAK3* or *STAT5B* and dual *JAK3/STAT5B* mutations are seen in 12% to 20% and 19% to 27% of cases, respectively.[90,152,155,158,174,175a] *STAT5B* mutations have been identified in lymphomas of all TR genotypes and more often in CD8αα-positive cases.[90,174] The higher VAFs of *STAT5B* mutations than of *JAK3* (and *SETD2*) mutations, in part caused by copy-neutral LOH, suggest an important role of mutation dosage in disease pathogenesis.[85,90,155,174]

DNA damage response and repair pathway genes are mutated in 33% to 44% of cases, including *ATM* (11%) and *TP53* (10%–44%).[85,89,90,152,155,158,174,175a] RAS-MAPK pathway mutations (30%–53%), targeting *KRAS* (10%–24%), *NRAS* (7%–20%), and *BRAF* (2%–27%), appear more frequent in this disease than in EATL.[85,89,90,152,155,158,174,175a] Mutations in *GNAI2,* which encodes the alpha subunit of guanine nucleotide binding proteins, reported in 9% to 24% of cases, have yet to be described in EATL.[152,155,158,174] *BCOR* mutations (11%) occur at a similar frequency as in EATL, but mutations in *DDX3X* (3%) are uncommon in MEITL.[155]

Higher transcript levels of *SYK, NCAM1* (CD56), *FASLG,* and *TGBR1* genes have been observed in MEITLs compared with EATLs,[85] and gene set enrichment analyses of MEITL transcriptomes have demonstrated enrichment in the NK-like cytotoxicity and JAK-STAT, GPCR, and MAPK signaling pathways,[85,174] in line with the proteomic and genetic alterations in these tumors.

Intestinal T-Cell Lymphoma, Not Otherwise Specified

A variety of PTCLs can secondarily involve the gastrointestinal tract and show overlapping histopathologic and immunophenotypic features with specific subtypes of intestinal T-cell lymphomas (see **Table 37-3**). At times, determining the primary site of these neoplasms can be difficult despite use of sensitive imaging modalities. Rarely, PTCLs characteristically occurring at other extranodal or nodal sites (e.g., extranodal NK/T-cell lymphoma,

nasal type, ALCL) may also arise in the gastrointestinal tract (see **Table 37-3**).[146,162,177] The diagnosis of intestinal T-cell lymphoma, not otherwise specified (ITCL, NOS), in essence, is one of exclusion and should be rendered for aggressive primary intestinal T/NK-cell lymphomas that on the basis of clinical, morphologic, and phenotypic criteria cannot be classified as any of the currently recognized entities.[6,7] The 2022 ICC and WHO 5th ed. classification have retained the term *ITCL, NOS*.[8] Importantly, this designation should be avoided when the biopsies are limited, precluding adequate morphologic and immunophenotypic evaluation.

Synonyms and Related Terms

WHO revised 4th ed., 2017: Intestinal T-cell lymphoma, not otherwise specified[6,7]

WHO 5th ed., 2022: Intestinal T-cell lymphoma, not otherwise specified[9]

The geographic distribution of ITCL, NOS is wide and this disease has constituted 18% to 44% of primary intestinal T-cell lymphomas in Asian series.[152,153,178] Patient demographics are largely similar to those described for EATL and MEITL, as are the clinical outcomes. ITCL, NOS can present as localized tumors or involve multiple gastrointestinal sites, more often in the colon and small intestine, and dissemination to regional lymph nodes and extragastrointestinal sites may be seen.[54,152,153,179] Symptoms and signs depend on the site and extent of disease. Some studies have reported lower rates of intestinal perforation in this subtype compared with EATL and MEITL.[152,153]

The cytomorphology of ITCL, NOS can vary and epitheliotropism is only observed in a minority of cases (≈20%).[54,179,180] The lymphomas are usually CD4 positive or CD4 negative/CD8 negative and a subset can express CD30. Although many exhibit a cytotoxic phenotype, lineage assignment may not always be possible as these tumors can lack TR expression (TR silent).[54] This entity is characteristically EBV negative and the occasional EBV-positive cases described likely represent gastrointestinal tract involvement by extranodal NK/T-cell lymphoma, nasal type.[180] Similar to other subtypes of primary intestinal T-cell lymphomas, targeted sequencing of a limited number of ITCL, NOS cases has revealed mutations in epigenetic regulators and JAK/STAT and RAS-MAPK pathway genes,[89,152,181] with one study reporting lower frequencies of *SETD2* and *STAT5B* mutations in this disease compared with MEITL.[152] Cases of ITCL, NOS may be reassigned to specific categories of intestinal T-cell lymphomas as our understanding of their clinical, morphologic, phenotypic, and genetic spectrum evolves (e.g., reclassification of primary intestinal TRγδ T-cell lymphomas and a subset of pleomorphic CD8-positive CD56-positive ITCLs as MEITLs).[152,159,182]

Indolent Natural Killer–Cell and T-Cell Lymphoproliferative Disorders of the Gastrointestinal Tract

A mucosal infiltrate of small or intermediate-sized lymphocytes in the gastrointestinal tract should raise the possibility of a primary indolent NK-cell or T-cell lymphoproliferative disorder (LPD) of the gastrointestinal tract (see **Table 37-3**). These LPDs can be

challenging to distinguish from inflammatory diseases, aggressive primary intestinal T-cell lymphomas, and extranodal NK/T-cell lymphoma, nasal type occurring in or involving the gastrointestinal tract (see **Table 37-3**). A detailed clinical history and knowledge of the clinical presentation are essential for appropriate diagnosis.

Indolent Natural Killer–Cell Lymphoproliferative Disorder of the Gastrointestinal Tract

An indolent NK-cell LPD involving the gastrointestinal tract was first described by Vega and associates in 2006.[183] Subsequently, case series from Japan[184,185] and the United States,[186-188] and isolated reports,[189-192] variably designated lymphomatoid gastropathy or NK-cell enteropathy, clarified the clinical, pathologic, and genetic features of this disease, prompting a change in nomenclature to *indolent NK-cell lymphoproliferative disorder of the gastrointestinal tract* and its inclusion as a distinct entity in the 2022 ICC and WHO 5th ed. classification.[8,9]

Synonyms and Related Terms

> Lymphomatoid gastropathy, NK-cell enteropathy (Obsolete)
> **WHO revised 4th ed., 2017:** Not included[6,7]
> **WHO 5th ed., 2022:** Indolent NK-cell lymphoproliferative disorder of the gastrointestinal tract[9]

Most of the indolent NK-cell LPDs have been reported from Asia and the United States.[192] However, recent publications suggest a broad geographic distribution.[86,193] These disorders are most often diagnosed in the 4th and 5th decades (range 14–75 years) and a

female preponderance has been noted in a few studies.[184-192] The etiology of indolent NK-cell LPDs is unclear. Patients with intestinal involvement lack evidence of celiac disease or inflammatory bowel disease, but a history of gastric cancer and presence of *Helicobacter pylori* infection has been documented in some patients with gastric disease. Symptoms and signs include abdominal pain or discomfort, diarrhea, rectal bleeding, and weight loss; however, some individuals may be asymptomatic.[191]

The stomach and intestines are commonly involved organs.[184-192] Rare cases have been reported in the gall bladder and cystic duct lymph node and also at extragastrointestinal sites.[187,194,194a] Superficial mucosal ulcers, erosions, or polyps can be observed on endoscopy.

Microscopic examination shows expansion of the lamina propria by an infiltrate of intermediate-to-large-sized cells that have round, oval or irregular nuclei, fine chromatin, inconspicuous or small nucleoli, and moderate pale cytoplasm (histiocytoid appearance) (**Fig. 37-19**). Eosinophilic cytoplasmic granules may be seen in a variable proportion of cells. Polymorphic infiltrates of histiocytes, plasma cells, and eosinophils and lymphoid aggregates are present at the periphery. Scattered apoptotic cells are observed, but in the absence of ulceration, necrosis is uncommon and angiocentricity or angiodestruction is not seen. Glandular displacement or destruction may be noted, but epitheliotropism is minimal or absent, and crypt hyperplasia and villous atrophy are not apparent when the small intestine is involved.[86,184-188]

The atypical lymphoid cells have an EBV– NK-cell phenotype (cytCD3+, sCD3–, CD5–, CD4–/CD8–, CD56+, TIA-1+, granzyme

B+, TR−) (**Fig. 37-19**; see also **Table 37-3**), and they do not express markers of T-cell or NK-T-cell subsets (TRαβ, TRγδ, CD161, CD158, TRVα24). Some cases display downregulation or loss of CD2, and expression of CD8 or CD16, and CD56 negativity may be seen occasionally.[185,194b] The Ki67 proliferation index is generally low (<40%).

In keeping with an NK-cell derivation, all cases analyzed have lacked clonal TR rearrangements. It is not known at present if indolent NK-cell LPDs arise from circulating, conventional NK cells or tissue-resident NK cells (or ILCs) in the gastrointestinal mucosa or at other sites.[128] It has been debated whether this disease represents an immune-mediated, reactive (polyclonal) condition or a clonal NK-cell proliferation. The recent identification of somatic genetic variants in 70% of cases, including activating *JAK3* mutations in 30% of cases, supports the latter view.[188] Moreover, detection of phospho-STAT5 expression in all evaluated cases indicates pervasive JAK3-STAT5 pathway activation in indolent NK-cell LPDs. The clinical course can vary, with spontaneous regression in most patients and occasional recurrences. Chemotherapy is not advised for disease management.

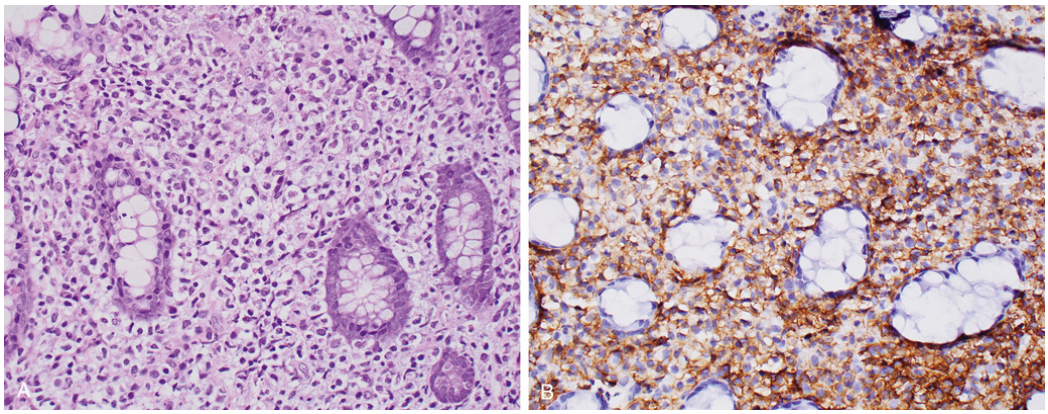

FIGURE 37-19 Indolent natural killer–cell lymphoproliferative disorder of the gastrointestinal tract.A, The colonic crypts are displaced by an infiltrate of medium-sized to focally large cells in the lamina propria that have ample clear or lightly eosinophilic cytoplasm, oval or irregular nuclei, fine chromatin, and inconspicuous or small nucleoli (histiocytoid appearance). **B,** The cells show variable intensity of CD56 expression.

Indolent Clonal T-Cell Lymphoproliferative Disorder of the Gastrointestinal Tract

Indolent *clonal* T-cell lymphoproliferative disorder (LPD) of the gastrointestinal tract is the new term for indolent T-cell lymphoproliferative disorder of the gastrointestinal tract in the 2022 ICC.[8] This disease, which was a provisional entity in the revised WHO 4th ed. classification,[6,7] was first described in 1994 by Carbonnel and coworkers, who later reported a series of four CD4-positive cases.[195] Subsequent case reports[191,192,194b, 196–202] and series[86,203-207] have documented the existence of CD4-positive,

CD8-positive, and occasional CD4-negative/CD8-negative and CD4-positive/CD8-positive lymphoid proliferations (**Fig. 37-20**; see also **Table 37-3**).

Synonyms and Related Terms

> **WHO revised 4th ed., 2017:** Indolent T-cell lymphoproliferative disorder of the gastrointestinal tract[6,7]
> **WHO 5th ed., 2022:** Indolent T-cell lymphoma of the gastrointestinal tract[9]

Indolent clonal T-cell LPD of the gastrointestinal tract has a wide geographic distribution and a slight male predominance, and similar to indolent NK-cell LPD of the gastrointestinal tract, is more frequently detected in the 4th and 5th decades (range 15–77 years).[195,203-205] The etiologies of the different phenotypic subtypes are not known. Some patients with CD8-positive LPDs have a history of inflammatory bowel disease, including a few having received immunomodulatory therapy, while infections or autoimmune disorders have been described in a subset of patients with CD4-positive LPDs.[194b,204,205,207,209] Chronic diarrhea, abdominal pain, and weight loss are common presentations.[191,192,207]

The small intestine or colon are common sites of disease, but any site in the gastrointestinal tract and multiple organs may be involved. Dissemination outside the gastrointestinal tract (e.g., bone marrow, tonsils, peripheral blood) is infrequent at diagnosis, however, it can occur at disease progression or transformation.[192,195,203-205] On endoscopy, the small intestinal mucosa can exhibit a mosaic appearance with loss of mucosal folds,

nodularity, or scalloping. Erythema, shallow ulcers, erosions, or multiple small polyps may also be seen at this and other locations.[191,192,195,203-205] Thickened intestinal folds, dilated intestinal loops, and enlarged abdominal lymph nodes are at times observed on imaging.[191,192]

On histopathologic evaluation, a mucosal and occasionally submucosal, nondestructive, EBV-negative, clonal lymphocytic infiltrate is seen, composed of mostly small-sized lymphocytes displaying minimal cytologic atypia (**Fig. 37-20**).[191] Patchy eosinophilia and scattered multinucleated giant cells or epithelioid granulomas may be present.[195,203,205] The mucosal architecture is generally preserved but some cases show villous atrophy or crypt hyperplasia. Intraepithelial lymphocytosis is uncommon; however, infiltration of the crypt epithelium is observed in a proportion of cases.

Indolent clonal T-cell LPD of the gastrointestinal tract is presumed to originate from lamina propria T-cells. CD8-positive cases usually display a type 2 effector and latent cytotoxic phenotype (TIA-1 positive, granzyme B negative, perforin negative),[207] similar to primary cutaneous acral CD8-positive T-cell LPDs,[210] while CD4-positive cases, although bearing some resemblance to primary cutaneous CD4-positive small or medium T-cell LPDs,[211,212] manifest a helper T-cell phenotype and lack evidence of follicular helper or regulatory T-cell derivation.[194b,202,203,207] Expression of CD2 and CD3 is almost universal, but variable downregulation or loss of CD5 or CD7 is seen in approximately 25% of cases, and rarely CD103 or CD20 expression may be observed.[194b] All phenotypic

subtypes express surface TRαβ, and they have low Ki67 labeling indices (<5%).

All evaluated cases have displayed clonal TRB or TRG rearrangements. Conventional cytogenetic analysis has revealed non-recurrent chromosomal abnormalities, with the exception of translocation t(9;17)(p24.1;q21.2) in CD4-positive LPDs that was later shown to represent a *STAT3*::*JAK2* fusion.[195,206,207,213] Single nucleotide polymorphism microarray investigations of CD4-positive cases have also demonstrated non-recurrent copy number changes[203,205]; however, some altered loci harbor genes of potential relevance to disease pathogenesis (e.g., 1p13/*SOCS1,* 17q21/*STAT3*), and copy number gains of 17q21/*STAT3* have been observed upon large cell transformation in two cases.[203,206] The spectrum of mutations and structural genetic variants differs in distinct phenotypic subtypes of LPDs.[86,206,207] *STAT3*::*JAK2* fusions have been identified in 45% of CD4-positive cases analyzed. The resultant chimeric protein retains many key functional domains of *STAT3,* including the SH2 domain, and *JAK2,* including the JH1 tyrosine kinase domain, and dimerization of the fusion protein preferentially activates STAT5 (over STAT3) enabling cytokine independent growth.[206,213a] Some CD4-positive LPDs lacking *STAT3*::*JAK2* fusions have other genetic alterations in the JAK-STAT signaling pathway (e.g., *STAT3* mutations).[207] Activating *STAT3* mutations have also been detected in CD4-positive/CD8-positive and CD4-negative/CD8-negative cases, but in none of the CD8-positive LPDs assessed thus far.[86,204,207] Mutations in epigenetic regulators (e.g., *TET2, KMT2D*) have been observed in all phenotypic subtypes of disease.[207,215] Structural alterations involving the 3′ untranslated

region of the *IL2* gene have been reported in a few CD8-positive LPDs.[207]

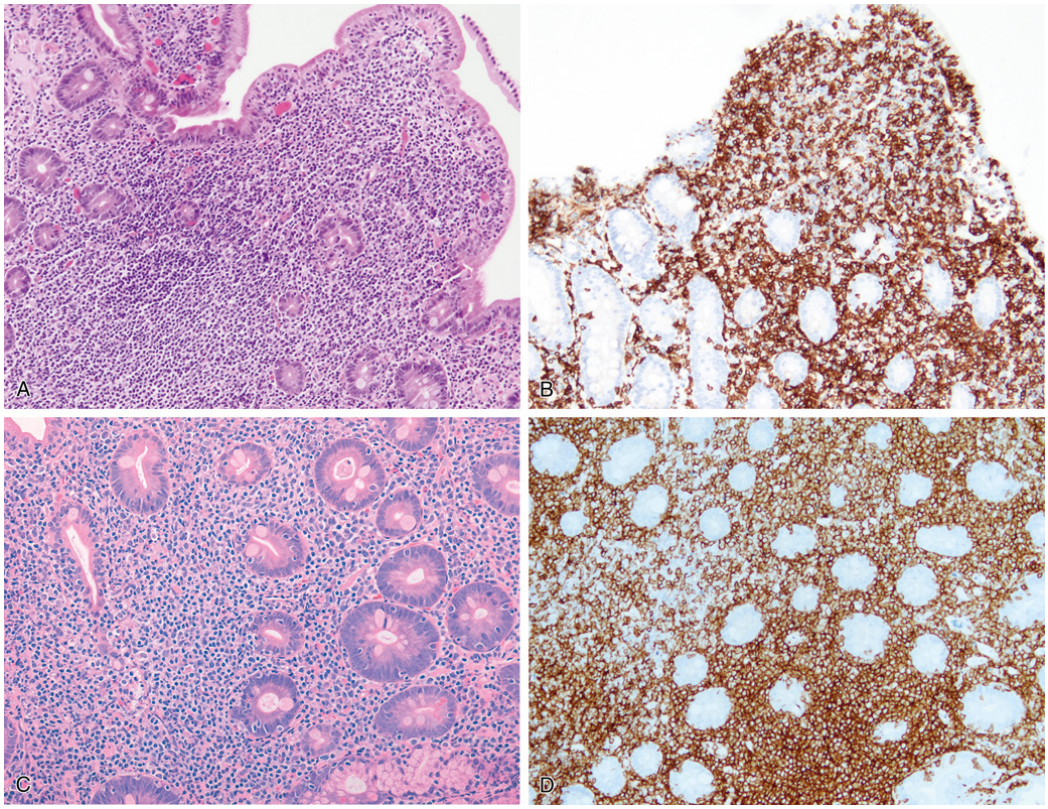

FIGURE 37-20 Indolent clonal lymphoproliferative disorder of the gastrointestinal tract.A, A dense infiltrate of predominantly small lymphocytes is seen in the jejunal lamina propria with focal infiltration of the villous and crypt epithelium. **B,** The neoplastic lymphocytes express CD8. **C,** Another case showing a small lymphocytic infiltrate in the duodenal lamina propria with infiltration of the crypt epithelium. **D,** The lymphocytes in this case express CD4.

Most patients do well with conservative management (e.g., luminal steroids) and have prolonged survival. The LPDs do not respond to chemotherapy and persist or recur after treatment in virtually all cases. Accordingly, the name *LPD* is preferred over *lymphoma* to deter aggressive therapy. Disease progression and, rarely, transformation to aggressive T-cell lymphoma can occur after many years, the latter having been reported in CD4-positive, CD8-positive, and CD4-negative/CD8-negative cases.[195,203,206,207,214,215]

Pearls and Pitfalls

- Enteropathy-associated T-cell lymphoma (EATL) is the most common (but not the only) intestinal T-cell lymphoma in Western countries.
- EATL is a rare complication of celiac disease that appears largely restricted to individuals of northern European origin.
- Monomorphic epitheliotropic intestinal T-cell lymphomas (MEITLs) have a wide geographic distribution and constitute a distinct subtype, unrelated to celiac disease.
- Indolent lymphoproliferative disorders of the gastrointestinal tract are rare clonal disorders that may be confused with inflammatory diseases or other aggressive types of intestinal T-cell lymphomas.
- The appropriate classification of intestinal T-cell lymphomas requires knowledge of their clinical presentation and

correlation of the cytomorphologic features with results of comprehensive immunophenotypic and molecular analyses.

Mycosis fungoides and Sézary syndrome are two closely related conditions in which neoplastic T cells infiltrate the skin and circulate in the peripheral blood. Both conditions are neoplasms that typically have a mature helper T-cell phenotype and a propensity to colonize the epidermis. Because individual patients can have discrete cutaneous lesions at one point in time and erythroderma with circulating neoplastic cells at another time, some advocate the term cutaneous T-cell lymphoma to describe what they consider to be a single disease.[1] However, the delineation of a variety of other distinct clinicopathologic entities that are also cutaneous T-cell lymphomas[2] has, in our opinion, rendered this term non-specific. We consider *cutaneous T-cell lymphoma* as an umbrella term that encompasses many different subtypes, including mycosis fungoides and Sézary

syndrome. Although Sézary syndrome was formerly considered to be a leukemic counterpart of mycosis fungoides,[3] more recent studies have demonstrated different molecular phenotypes in these two conditions.[4,5] Furthermore, they have very different clinical presentations. Therefore, these conditions are now considered to be different diseases. This chapter covers mycosis fungoides and its many variants and Sézary syndrome.

Mycosis Fungoides

Definition

Mycosis fungoides is a T-cell lymphoma in which lymphocytes infiltrate the epidermis in its early stages, resulting in flat, often slightly scaly lesions (patches). In some patients, lymphocytes acquire the ability to proliferate in the dermis, forming plaques and nodules. A small minority of patients will have involvement of internal organs in the course of their disease. The neoplastic cells in mycosis fungoides are skin resident effector memory T-cells.[6] Most cases of mycosis fungoides have a T-helper phenotype, but clinically and histopathologically identical infiltrates can be seen in which the neoplastic cells are CD8 positive or CD20 positive. Our view, which is not shared by all authorities, is that the clinical evolution of patches to plaques and tumors determines whether a patient has the disease mycosis fungoides, not a specific immunophenotype. If a patient has indolent patches in which there are epidermotropic CD8-positive T cells, there is no harm in labeling that mycosis fungoides. Indeed, in many centers, immunophenotypic studies are not routinely performed, and patients are treated with excellent results. The term *mycosis fungoides* does not apply, however, to a disease

caused by infection with the retrovirus human T-lymphotropic virus 1 (HTLV-1), despite the clinical and pathologic resemblance of some cases; that condition is referred to as *adult T-cell leukemia/lymphoma*. The major diagnostic features of mycosis fungoides are listed in **Box 38-1**.

Epidemiology

Mycosis fungoides is largely a disease of middle-aged and older people. However, as clinicians and pathologists have become more adept at recognizing its early stages, more cases in young adults and even in children have come to light. The incidence of mycosis fungoides in a population is certainly affected by the number of dermatologists in the community, their interest in and awareness of the disease, and their threshold for diagnosis. An interesting observation is that the incidence of mycosis fungoides rose rapidly in the early 1980s,[7] coincident with the delineation of criteria for the diagnosis of patch-stage disease by Sanchez and Ackerman.[8] After the publication of their paper, many pathologists began to diagnose mycosis fungoides on the basis of infiltrates they might have previously regarded as parapsoriasis en plaques or inflammatory conditions, such as spongiotic dermatitis. The increased incidence of mycosis fungoides in the United States seems to reflect a rise in the detection and diagnosis of early patch-stage disease.

Box 38-1 Key Diagnostic Features of Mycosis Fungoides

Clinical Features

Patch stage: Patches with fine overlying scale, often more than 5 cm in diameter in photoprotected sites
Plaque stage: Same location and size as patches, but lesions are thicker with induration and elevation
Tumor stage: Solid nodules at least 1 cm in diameter that usually develop in patches and plaques

Histopathologic Features

Patch stage: Sparse perivascular to bandlike infiltrate of lymphocytes with variable infiltration of the epidermis and variable cytologic atypia
Plaque stage: Infiltrate denser and extends into reticular dermis
Tumor stage: Diffuse infiltrate extending throughout the reticular dermis

Immunohistochemical Features

βF1-positive, CD3-positive, CD4-positive, CD8-negative immunophenotype is most common, but variations in otherwise typical disease occur and have little meaning

Genotypic Findings

Demonstrable clonality common but not obligatory by polymerase chain reaction (PCR)–based gamma alone or gamma plus beta chain gene rearrangements

Etiology

A number of investigators have tried to link mycosis fungoides to environmental exposures, without success. Studies to determine whether common inflammatory skin diseases, such as atopic dermatitis, chronic allergic contact dermatitis, and psoriasis, give rise to mycosis fungoides are undermined by several factors. Early patches of mycosis fungoides can resemble these diseases clinically, so a patient with a 20-year history of "atopic dermatitis" preceding mycosis fungoides might have had patches of mycosis fungoides that were simply not recognized as such. Early patch-stage lesions of mycosis fungoides can resemble various inflammatory conditions under the microscope, so that even "biopsy-proven" psoriasis may not be that disease at all.

Several studies have sought the presence of a virus in the cells of mycosis fungoides. In the 1970s, interest centered on the identification of viral particles in skin biopsy samples of mycosis fungoides by electron microscopy.[9] Later, interest focused on a possible role for HTLV-1, the retrovirus that causes adult T-cell leukemia/lymphoma, in mycosis fungoides.[10] An initial study seemed to identify partial viral transcripts in the cells of mycosis fungoides, but further investigation has not borne this out in most cases. Another theory related to infection is that mycosis fungoides is an abnormal response to bacterial superantigens, in particular *Staphylococcus aureus*.[11]

Clinical Features

Mycosis fungoides is largely defined by the clinical features of its early stages. Requisite to this definition is an initial presentation as flat, scaly lesions called *patches*. These first appear in areas of the

skin that are best protected from sunlight—the buttocks and groins of both sexes and the breasts of women. Subtle wrinkling, slight erythema, telangiectasias, and either hypopigmentation or hyperpigmentation are variable findings. Often, the patches are so subtle that patients do not notice them for some time, and both patients and their physicians may attribute the condition to dry skin or atopic dermatitis. Patches are generally round or oval, although they are sometimes finger shaped or digitate (**Fig. 38-1**). Their size can range from about 1 cm to more than 15 cm.

Some clinicians use the term *small plaque parapsoriasis* to refer to small patches (smaller than an adult palm) and the term *large plaque parapsoriasis* to refer to larger lesions of patch-stage mycosis fungoides. Those who think that mycosis fungoides begins as an inflammatory condition that may regress often use the term *parapsoriasis*. This usage originated with the work of the French dermatologist Brocq in the late 19th and early 20th centuries. He envisaged a complex relationship among psoriasis, eczema, seborrheic dermatitis, the conditions now known as pityriasis lichenoides acuta and chronica, and mycosis fungoides.[12] In our opinion, the term *parapsoriasis* is invalid scientifically, although it may have some functional utility in that it is shorthand for "I suspect that this is an early patch of mycosis fungoides but am not sure." This dilemma is better expressed in clear language, however. Confounding this already confusing situation is the older use of the term *parapsoriasis lichenoides* to refer to pityriasis lichenoides, an inflammatory disease.

Digitate or finger-shaped patches may occur by themselves in a condition called *digitate dermatosis*. It was initially reported that it

should be separated from “true” parapsoriasis and be considered as a benign dermatosis.[13] Later, it was noted that similarly shaped patches can be found alongside conventional lesions of mycosis fungoides. This led some observers to conclude that digitate dermatosis is in fact a form of mycosis fungoides.[14] Because the prognosis of patients with only digitate lesions is excellent and the histopathologic findings are often paltry, others question the usefulness of labeling patients with digitate dermatosis as having mycosis fungoides.[15] There are, however, patients who present with small digitate lesions and develop recognizable mycosis fungoides or even erythroderma.[16,17] Whether these patients truly presented with digitate dermatosis or had digitate lesion of mycosis fungoides from the outset is difficult to know. Many authors regard small plaque parapsoriasis either as a spongiotic dermatitis or as an “abortive” cutaneous T cell lymphoma, a lymphoproliferative disease that rarely progresses.[18,19]

FIGURE 38-1 Patches of mycosis fungoides often arise on double-clothed areas, and the lesions may recede with light exposure.**A,** Classic patches are often the size of a palm or larger. **B,** Digitate lesions of mycosis fungoides are so called because they are finger-shaped patches, often aligned along Langer's lines.

In some patients with preexisting patches of mycosis fungoides and in others who claim that they never had such patches, areas of the skin can become thin and wrinkled and marked by macules of hypopigmentation and hyperpigmentation, along with telangiectasias. This appearance is known as *poikiloderma* or *poikiloderma vasculare atrophicans*. It appears to be a manifestation of regression of patch-stage mycosis fungoides.

The large majority of patients with mycosis fungoides who have patches over a small area of skin at presentation prove to have an

indolent condition that seldom becomes more than a cosmetic problem, even if it is untreated. In a minority of such patients, disseminated patches arise.

Plaques of mycosis fungoides are usually located in the same locations as patches but differ from patches in that they are raised. Plaques are varying shades of red to red-brown and scaly. They are often polycyclic, with clearing in the center (**Fig. 38-2A**). They sometimes ulcerate, but not as much as nodules or tumors do.

Tumors of mycosis fungoides are raised nodules that are often smooth but frequently ulcerate (**Fig. 38-2B**). They are clinically indistinguishable from nodules and tumors of other cutaneous lymphomas. However, tumors almost invariably arise within or adjacent to preexisting patches and plaques of mycosis fungoides, and thus a careful clinical examination to assess for concomitant patches and plaques can be helpful to distinguish tumors of mycosis fungoides from other cutaneous lymphomas. The tumors can sometimes assume a mushroom-like configuration, and this attribute resulted in Alibert giving the condition the name *mycosis fungoides.*[20]

Histopathology

There is vast variability in the histopathologic appearance of mycosis fungoides, especially in patch-stage disease. This reflects the fact that early lesions may be composed largely of non-neoplastic cells, exerting their influence through cytotoxicity and cytokine production and in ways not yet appreciated.

The early patches of mycosis fungoides feature lymphocytes that are not usually morphologically atypical and thus can appear similar

to those found in inflammatory skin diseases. In fact, studies have demonstrated that 4% (27 of 745) of biopsy specimens of early mycosis fungoides reviewed had atypical lymphocytes within the epidermis.[21] Therefore, identification of a section as representing early mycosis fungoides, either definitely or possibly, usually requires attention to the histopathologic pattern of the infiltrate rather than the identification of atypical lymphocytes.

The earliest patches of mycosis fungoides feature small lymphocytes around venules of the superficial plexus; some are scattered interstitially in the papillary dermis, with only a few within the epidermis (**Fig. 38-3**). In some cases, when the cells of mycosis fungoides enter the epidermis, they can elicit spongiosis or edema between keratinocytes. The degree of spongiosis is usually less than that seen when the same number of lymphocytes enter the epidermis in an inflammatory skin disease. The tendency of the cells of mycosis fungoides to colonize the epidermis is referred to as *epidermotropism*. This term is also used to connote that there are areas of the epidermis that have only slight spongiosis and many lymphocytes. *Exocytosis* describes the migration of inflammatory cells into the epidermis and is a more neutral term. Because the term *epidermotropism* presupposes the ultimate diagnosis, it is best avoided if the diagnosis of mycosis fungoides is equivocal.

FIGURE 38-2 **A,** Plaques of mycosis fungoides often have a polycyclic appearance. **B,** Tumors are more elevated above the skin surface and usually arise within or adjacent to preexisting patches and plaques of mycosis fungoides.

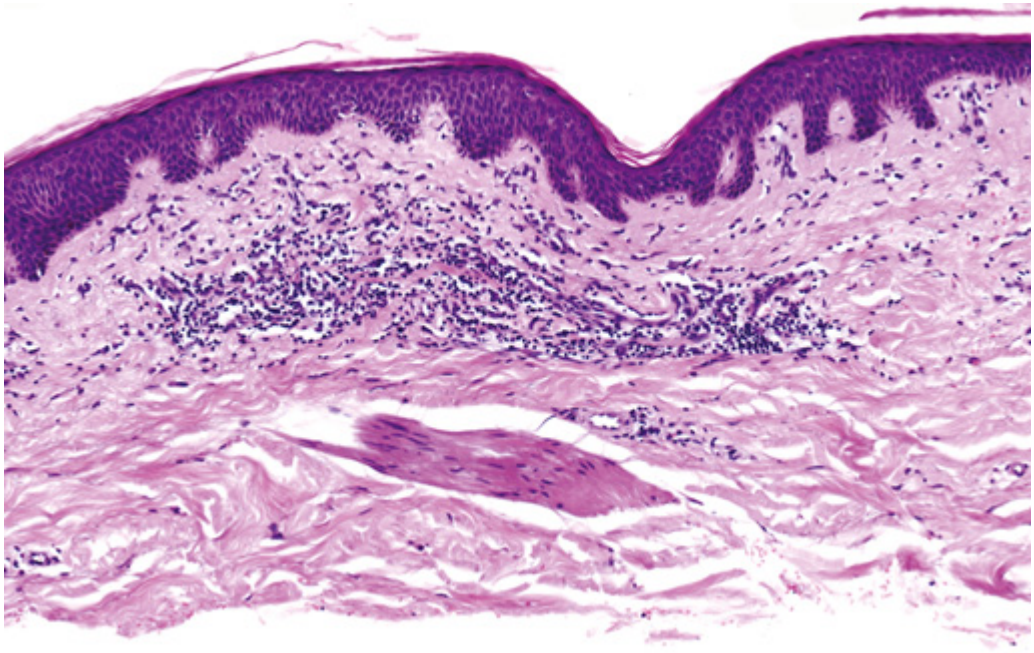

FIGURE 38-3 Early patch of mycosis fungoides featuring a psoriasiform lichenoid pattern, with small lymphocytes in a band in the papillary dermis and only a few in the epidermis. An unequivocal diagnosis is not possible in this case.

In early patch-stage disease, mycosis fungoides is often not recognizable with certainty. As the patches develop, the papillary dermis becomes fibrotic. The collagen bundles of the papillary dermis are usually fine and haphazardly oriented. This meshwork changes to one in which there are coarse fibers sometimes likened to "pink fettuccini." At the same time, rete ridges begin to elongate, usually only slightly and very evenly. Their bases remain rounded, unlike in many interface dermatitides. Lymphocytes may lodge in the basal layer of the epidermis, with only slight vacuolar changes and few necrotic keratinocytes.[22]

The papillary dermal lymphocytic infiltrate often becomes bandlike, at least in foci. The combination of elongated rete ridges with rounded bases and bandlike lymphocytic infiltrates is known as a *psoriasiform lichenoid pattern;* if spongiosis is also present, it is referred to as a *spongiotic psoriasiform lichenoid pattern*. If the lymphocytes engaged as a host response to the neoplasm kill keratinocytes that constitute rete ridges, the epidermis may become thin and flat based—an *atrophic lichenoid pattern*. These three patterns should raise the pathologist's suspicion that he or she may be dealing with a lesion of mycosis fungoides because only a few inflammatory skin diseases share these patterns (**Box 38-2**).

As the infiltrates of mycosis fungoides become dense and bandlike in the papillary dermis, they also begin to exhibit cells with atypical nuclei (**Fig. 38-4**). Cells of patch-stage mycosis fungoides have slightly larger nuclei than those of lymphocytes in inflammatory conditions, with an irregular nuclear contour—the so-called "cerebriform lymphocyte" (**Fig. 38-5**). An important caveat is that if nuclear atypia is used as a criterion for the differential diagnosis between a patch of mycosis fungoides and an inflammatory condition, the atypia must be unmistakable. Many pathologists can convince themselves that the nuclei of lymphocytes are atypical by staring at them for too long under an oil immersion lens.

Some patches of mycosis fungoides feature epidermal atrophy, in concert with a patchy lichenoid lymphocytic infiltrate. The papillary dermis is often markedly fibrotic and contains telangiectasias and melanophages, corresponding to the clinical picture of poikiloderma vasculare atrophicans. In such atrophic patch-stage lesions, it may be difficult to demonstrate a sufficient number of lymphocytes in the

epidermis to rule out an inflammatory disease with an atrophic lichenoid pattern (**Box 38-2**).

In plaques of mycosis fungoides, lymphocytes extend into the reticular dermis, not only around vessels but also interspersed between reticular dermal collagen bundles (**Fig. 38-6**). This finding occurs beneath an epidermis and papillary dermis displaying the changes described for fully developed patches of mycosis fungoides. Although lymphocytes with atypical nuclei are few in early patches and more numerous in late ones, they almost always constitute a significant percentage of the infiltrate in plaques. Similarly, aggregations of lymphocytes, termed *Pautrier's microabscesses* or *collections*, are rare in patches but common in plaques. Interestingly, this distinctive clue to the diagnosis of mycosis fungoides was discovered not by Pautrier but by Darier.[23] The atypical lymphocytes of patches have scant cytoplasm and irregular, sometimes cerebriform lymphocytes. By contrast, in plaques, some of the lesional lymphocytes can have large vesicular nuclei, large nucleoli, and some discernible cytoplasm, and with larger cerebriform cells than are seen in patches. Furthermore, in contrast to patches, which lack eosinophils and plasma cells, plaques and tumors of mycosis fungoides often have many of these cells. This might correlate with a shift from Th1 to Th2-like cytokine production as lesions change from patches to plaques.

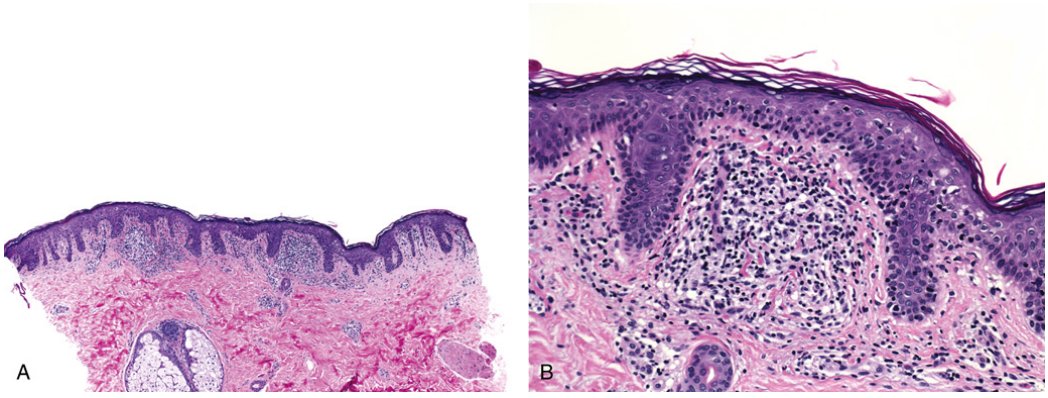

FIGURE 38-4 **A,** Later patch of mycosis fungoides, again with a psoriasiform lichenoid pattern. **B,** In this lesion (unlike that in Fig. 38-3), many lymphocytes infiltrate the epidermis, with only scant spongiosis. Those in the epidermis have slightly larger and darker nuclei than those in the dermis.

Box 38-2 Common Patterns of Patch-Stage Mycosis Fungoides and the Inflammatory Skin Diseases That Share Them

Psoriasiform Lichenoid Pattern

Mycosis fungoides, patch stage
Secondary syphilis (usually superficial and deep, with many plasma cells and histiocytes)
Lichenoid purpura (extravasated erythrocytes and siderophages)
Lichen striatus (linear eruption of papules in a child or teenager)

Early lesions of lichen sclerosus et atrophicus
Surface of some lesions of morphea
Drug reaction (one pattern among many)

Spongiotic Psoriasiform Lichenoid Pattern

Mycosis fungoides, patch stage
Urticarial stage of bullous pemphigoid
Drug reactions (one pattern among many)
Allergic contact dermatitis (rare; so-called “lichenoid contact dermatitis”)
Chronic photoallergic dermatitis (actinic reticuloid)

Atrophic Lichenoid Pattern

Mycosis fungoides, atrophic patch stage
Atrophic lichen planus
Lichenoid purpura
Regression of melanoma, Bowen’s disease, superficial basal cell carcinoma
Centers of lesions of porokeratosis (sometimes)
Poikilodermatous lesions of dermatomyositis

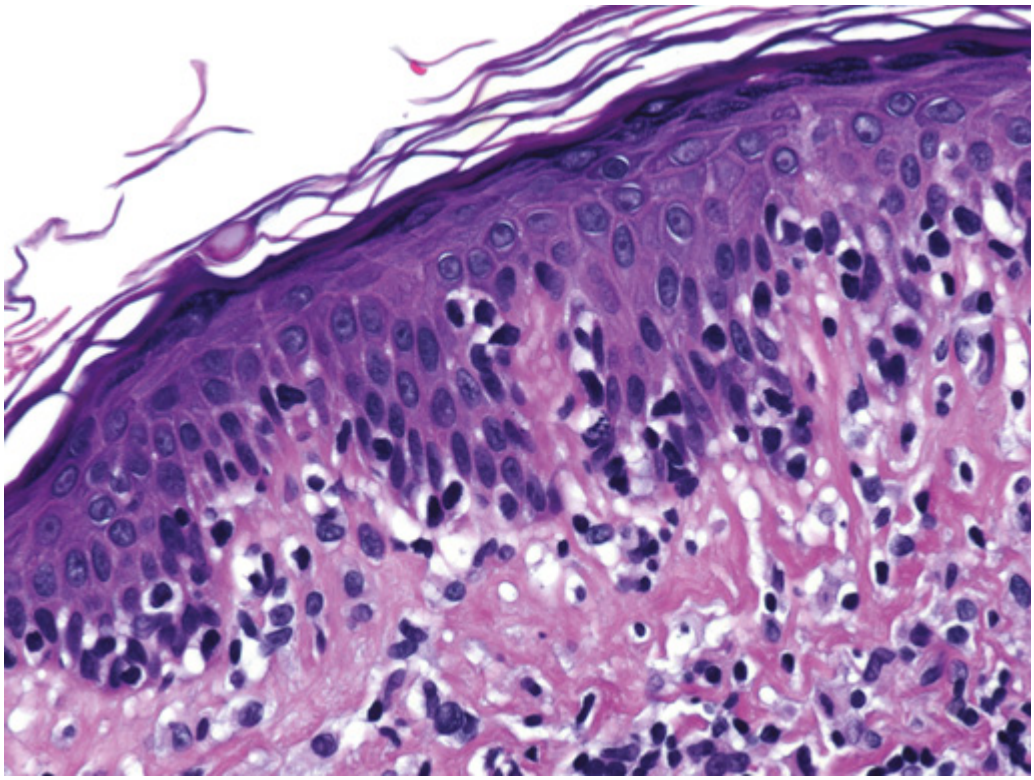

FIGURE 38-5 Lymphocytes in the epidermis of a patch of mycosis fungoides with scant cytoplasm and large hyperchromatic nuclei. Small halos are present around some of them.

Nodules or tumors of mycosis fungoides acquire their clinical features by virtue of lymphocytic infiltrates that are present as nodules or diffusely replace the reticular dermis (**Fig. 38-7**). Large cell transformation, defined as when more than 25% of the infiltrate is composed of large cells, can occur in tumors of mycosis fungoides.[24] The appearance of the large cells ranges from cells with large round or slightly oval vesicular nuclei and scant cytoplasm to cells with large oval vesicular nuclei, large nucleoli, and abundant cytoplasm, similar to the cells of anaplastic large cell lymphoma. This usually occurs in advanced disease and may have an adverse

prognostic effect. Nevertheless, large cell transformation can occasionally occur in patches and plaques as well, although less commonly than in tumors (**Fig. 38-8**).[25,26] While increased expression of CD30 can occur in large cell transformation, the definition of large cell transformation is based on morphology and not on the status of the CD30 on the lesional lymphocytes.

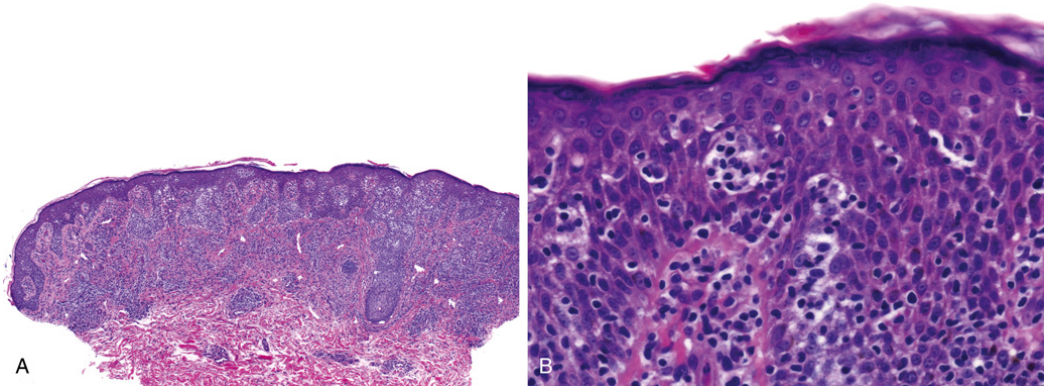

FIGURE 38-6 **A,** Plaque-stage mycosis fungoides features infiltration of the superficial reticular dermis. **B,** In this case, there are prominent collections of lymphocytes (Pautrier's microabscesses) in the epidermis as well.

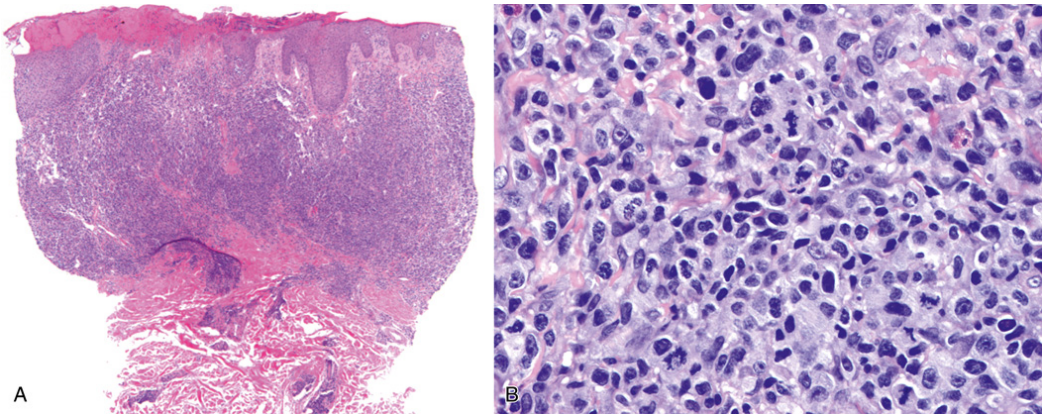

FIGURE 38-7 **A,** Mycosis fungoides tumor with diffuse infiltration of the dermis. Tumors sometimes ulcerate, as in this case. There may be a variety of cytomorphologic findings in the lymphocytes of tumor-stage lesions, but large cerebriform cells or cells with large vesicular nuclei usually predominate. **B,** The lesional lymphocytes often are markedly atypical, and numerous mitotic figures are evident among them.

Anaplastic large cells may predominate to such an extent that only the clinical identification of patches or plaques at other sites allows the distinction from anaplastic large cell lymphoma. Although lymphocytes home to the epidermis in patch-stage and plaque-stage lesions, some tumors of mycosis fungoides completely lack intraepidermal lymphocytes. The loss of dependence on an epidermal environment for cellular proliferation in the skin occurs apace with the cells' capacity to lodge in internal organs in mycosis fungoides.

Grading

Although biopsy interpretation is critical in establishing a diagnosis of mycosis fungoides, little prognostic information can be gleaned from histopathologic sections. Whether a patient has patches, plaques, or tumors can be determined clinically (there are a few pitfalls, however, such as mistaking lesions elevated by comedones for nodules). Most studies have demonstrated that the detection of transformed lymphocytes in plaques and tumors of mycosis fungoides has an adverse effect on survival.[25,26] However, it has been recognized that a subset of patients with histopathologic evidence of transformation has an indolent clinical course.[27]

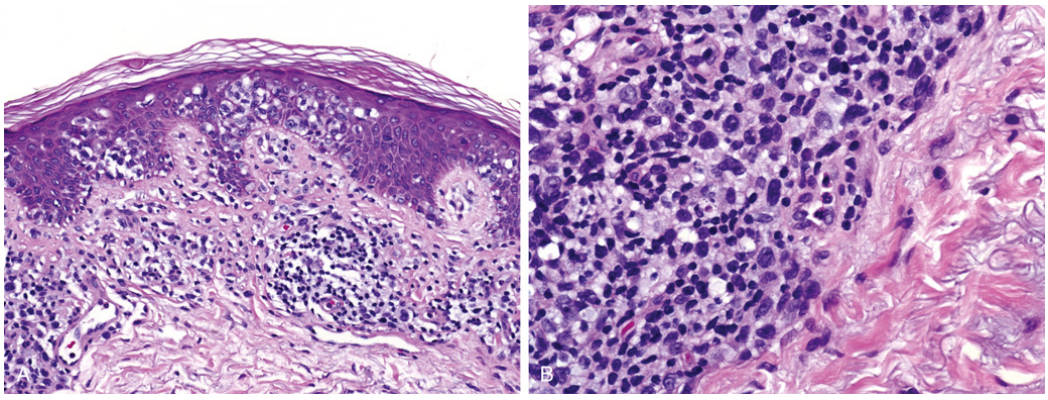

FIGURE 38-8 **A,** Thin plaque of mycosis fungoides with large cell transformation. **B,** Although the infiltrate is sparser than that of the plaque in Figure 38-6, many lymphocytes have large, vesicular nuclei with prominent nucleoli.

Immunophenotype

The cells of mycosis fungoides are mature helper T cells in the large majority of cases, with a βF1-positive, CD3-positive, CD4-positive,

CD8-negative phenotype. Patches of mycosis fungoides usually have neoplastic cells that express the normal panoply of T-cell antigens, such as CD2 and CD5, but may not express CD7.[28] Some papers refer to a “loss” of CD7, whereas others view mycosis fungoides as a neoplastic expansion of the normally occurring (but minority population) of CD7-negative helper T cells. Whether the finding of large numbers of CD3-positive, CD4-positive, CD7-negative cells in a cutaneous infiltrate is diagnostic of mycosis fungoides is controversial. There are practical impediments to the implementation of this finding as a diagnostic criterion, even if it were a scientifically valid concept. Nevertheless, some groups have published results suggesting that CD7 staining in paraffin embedded sections may be helpful in the diagnosis.[29] Well-developed patches, plaques, and tumors may show a high CD4:CD8 ratio, and loss of pan–T cell antigens. However, in early lesions, there may be more reactive than neoplastic cells, making it difficult to assess the immunophenotype of the putative neoplastic cells. In our experience, only rarely is there enough of an altered CD4:CD8 ratio, enough cells with a double negative (CD4 negative, CD8 negative) immunophenotype or loss of pan–T cell antigens for immunostaining to be decisive in difficult cases.

As noted, a variety of immunophenotypes can occur in patients who, on clinical grounds and by conventional histopathologic examination, seem to have mycosis fungoides. These include CD8-positive and even CD56-positive immunophenotypes. How common this situation is depends on how many cases are tested with these antibodies. CD8-positive cases usually have a cytotoxic immunophenotype. CD56-positive cases are rarer and can have

several different immunophenotypes, including CD4 positive and CD8 positive.[30]

Plaques and tumors of mycosis fungoides often have other aberrations—diminished expression of CD5, CD2, or even CD3—but by the time these findings are present, the diagnosis can be easily established by routine methods. A cytotoxic phenotype with T-cell intracellular antigen-1 and granzyme B expression can occur in later stage lesions.[31]

CD30 is an antigen expressed on the cells of Hodgkin lymphoma and by those of anaplastic large cell lymphoma. Its presence is not specific, and it is also expressed by lymphocytes that have been stimulated by antigen in infectious and inflammatory conditions. CD30-positive cells occur in some plaques of mycosis fungoides, but mostly in tumors that have anaplastic large cells. There seems to be no prognostic significance to CD30 expression in mycosis fungoides when it is detected in patches.[32] However, when CD30 is expressed on lesional lymphocytes that have undergone large cell transformation, it does seem to have prognostic significance as one study demonstrated that CD30 expression is associated with improved survival compared with lack of CD30 expression.[27] Brentuximab vedotin is a relatively new medication that is a monoclonal antibody directed at CD30, and which is used to treat some lymphomas that express CD30. Therefore the CD30 status of an infiltrate of mycosis fungoides may now be relevant to treatment. As such, clinical teams may request staining with this antibody.[33]

Programmed death 1 (PD-1, CD279), a member of the CD28/CTLA-1 receptor family, is thought to play an important role in the inhibition of T-cell activity.[34,35] Studies have demonstrated

disparate findings with regard to the expression of PD-1 on the lesional lymphocytes in mycosis fungoides; some reports document relatively high rates of expression of PD-1 (40% of patches and plaques and 60% of tumors),[35] whereas others show low rates of expression (13% of patches and plaques and 14% of tumors).[36] Other antigens associated with T follicular helper cells including ICOS, BCL6, CXCL13, and even CD10 have also been reported in variable proportions in biopsies of mycosis fungoides.[36,37]

Genotypic Features

Mycosis fungoides cells have undergone rearrangement of their T-cell receptor genes, even though this cannot always be documented. It is also important to recognize that T-cell clonality may be demonstrable in inflammatory skin disorders of various kinds, with precise specificity and sensitivity depending on both technical factors and the extent of the neoplastic infiltrate.[38,39] Many laboratories currently use polymerase chain reaction (PCR)–based methods from paraffin embedded tissue for this testing. Depending on how they are analyzed, the addition of probes for T-cell receptor beta genes to those for T-cell receptor gamma genes can lead to an increase in specificity, but at a loss of sensitivity.[39] An increase in sensitivity may be achieved but at some loss of specificity. It is therefore important that PCR be applied judiciously to cases in which mycosis fungoides is compatible clinically and suspected microscopically. An algorithm for how to interpret PCR findings based on pretest probability for mycosis fungoides has been suggested.[39] Next-generation sequencing is currently used at some centers to assess for

T-cell clonality and may be a technology that replaces PCR-based assays in the future for T-cell clonality assessment.[40,41]

Much has also been learned about genetic and epigenetic abnormalities in mycosis fungoides using next-generation sequencing and other technologies. This has been recently reviewed.[42]

Postulated Cell of Origin

Mycosis fungoides is considered a neoplasm of skin resident effector memory T-cells (CCR7/L-selectin and CD27 negative, but showing strong expression of CCR4 and CLA).[6] They usually represent activated, mature helper T cells. Attention has been given to the role of T regulatory cells in several inflammatory skin diseases and in mycosis fungoides. It appears that these cells, which are positive for CD25 and FOXP3, may play a role in mycosis fungoides.[31,43]

Clinical Course

Most of the literature written before 1980 applies to patients with plaques and tumors because the patch stage was not widely recognized before that time. Many of these early studies reported a grim prognosis for patients with mycosis fungoides, and the more recent decline in mortality[44] seems to be caused by recognition of the disease at an earlier stage rather than to better treatments.

More current studies have demonstrated that patients with patches of mycosis fungoides often have indolent disease for many years; if the condition is limited to less than 10% of the body surface, lifespan is often unaffected.[45] Those with more extensive patches are more likely to develop plaques, tumors, and internal disease.

Patients with disseminated plaques, tumors, or both may develop internal disease. This can take the form of adenopathy, hepatosplenomegaly, or infiltrates in other organs that can be detected only by biopsy or necropsy. The most serious effects are on the immune system, however. Although the peripheral helper T-cell counts of patients with mycosis fungoides may be nearly normal or high, those with advanced disease often have diminished numbers of functional T-helper cells. Those in the blood may be neoplastic cells, which cannot respond effectively to infection. In its terminal stages, mycosis fungoides results in death from immunodeficiency.[46] The 5-year and 10-year overall survival in tumor-stage MF has been reported as 40% to 65% and 20% to 39%, respectively, and the mean survival in tumor-stage MF has been reported at 2.9 to 4.7 years.[46a]

Differential Diagnosis

A number of inflammatory skin conditions simulate mycosis fungoides clinically, pathologically, or both. Knowledge of the differential diagnosis of mycosis fungoides is most critical in these circumstances for recognition of its patch stage.

The skin diseases that simulate the patch stage of mycosis fungoides result in macules or patches of slightly inflamed, scaling skin. These include forms of spongiotic dermatitis, such as allergic contact or nummular dermatitis; pityriasis rosea; and interface dermatitides, such as lichenoid drug eruptions. Spongiotic dermatitis usually has perivascular rather than bandlike infiltrates in the superficial dermis, as well as areas with abundant spongiosis without many lymphocytes. A helpful feature in some cases is the presence of eosinophils. Early patches of mycosis fungoides seldom have more

than a few eosinophils.[47] Although spongiotic dermatitides may lack eosinophils entirely, many cases have eosinophils in both the dermis and (if one looks carefully) the epidermis.

One pitfall posed by the spongiotic dermatitides is the presence of collections of pale-staining mononuclear cells in the epidermis (**Fig. 38-9**). These collections, composed of Langerhans cells and their monocytic precursors, have a heterogeneous composition.[48] Their cells have pale cytoplasm and reniform vesicular nuclei. True Pautrier's microabscesses or collections in mycosis fungoides are compactly arranged aggregations in which lymphocytes predominate. The cells have scant cytoplasm, and the nuclei are darker than in so-called "Langerhans cell pustules." Another clue is the shape of the aggregations. True Pautrier's microabscesses are round, whereas their spongiotic counterparts often have a vaselike shape, with everted lips on the epidermal surface.[48] In the rare case when immunohistochemistry is used to distinguish between Pautrier's microabscesses and Langerhans cell pustules, Pautrier's microabscesses are composed mostly of cells that stain for CD3, and Langerhans cell pustules are composed of cells that stain for either CD1a, langerin, or CD68. A Langerhans cell is usually found at the center of each Pautrier's microabscess.

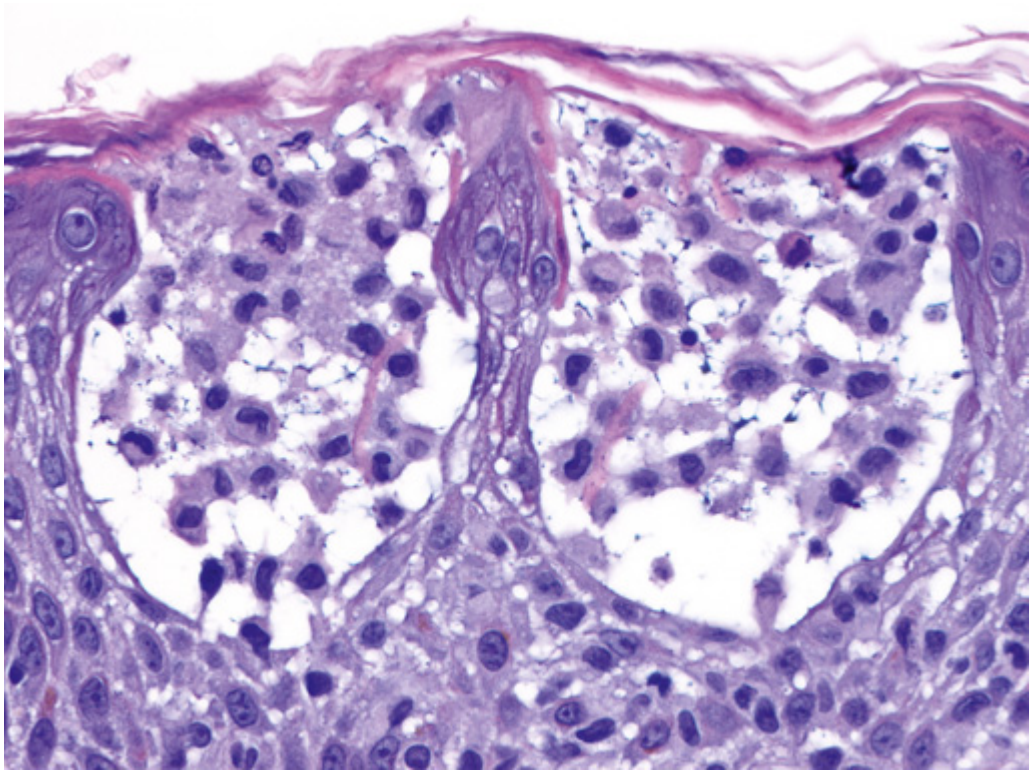

FIGURE 38-9 Vase-shaped collection of Langerhans cells in spongiotic dermatitis.

Interface dermatitides are a clinically diverse group of diseases in which lymphocytes obscure the dermoepidermal junction. The consequences of this infiltration include vacuolar change, an alteration in the shape of rete ridges (they become serrated or recede entirely), and cytotoxic damage to keratinocytes, visible as dyskeratotic cells in the epidermis and as colloid bodies when these descend into the papillary dermis. Small foci with these findings commonly occur in mycosis fungoides. They are seldom the dominant feature in all lesions of a single patient, although there is a rare variant in which such changes occur (**Fig. 38-10**).[49] It cannot be overemphasized, however, that a single biopsy specimen from a patient with mycosis fungoides can show an interface pattern and

that several biopsy specimens must be obtained if mycosis fungoides is suspected clinically.[21] Pathologists unfamiliar with lichen planus, lichenoid drug eruptions, lichenoid keratoses, and even densely infiltrated lesions of lupus erythematosus may mistake these lesions for mycosis fungoides owing to numerous lymphocytes in the lower part of the epidermis in such cases. Lichenoid keratoses may present a particular diagnostic challenge because they can feature many lymphocytes in the epidermis.[50] An important reminder is that mycosis fungoides does not present as a small solitary keratosis (in the solitary variant of mycosis fungoides, the lesions are usually relatively large in size).

There are several inflammatory diseases that cause a psoriasiform lichenoid pattern or a psoriasiform lichenoid spongiotic pattern, the most common patterns in patches of mycosis fungoides. In some cases, lymphocytes even lie in the basal layer of the epidermis in a linear fashion ("beads on a string"), without the same degree of vacuolar change or number of necrotic keratinocytes seen in most interface dermatitides. Luckily, many of these conditions do not simulate mycosis fungoides clinically. Lichen striatus, for example, causes linearly arranged papules along Blaschko's lines in children and adolescents more often than in adults.[51] Lichen sclerosus et atrophicus has an inflammatory phase that can mimic mycosis fungoides, but solitary lesions of mycosis fungoides on the skin of the genitalia essentially do not occur. Extragenital lichen sclerosus may present problems in this regard, especially if it is sampled by a thin shave biopsy.[52]

Among the most treacherous entities with a psoriasiform lichenoid pattern are members of a group of conditions termed *persistent*

pigmented purpuric dermatitis.[53,54] These diseases usually affect the skin of the legs, resulting in red to rust or golden-brown macules, papules, and sometimes plaques. They are caused by infiltrates of lymphocytes that somehow induce venules to leak red blood cells into the dermis. Over time, siderophages accumulate. Two forms—lichenoid purpura of Gougerot and Blum and lichen aureus—have dense, bandlike infiltrates of lymphocytes, sometimes in a fibrotic and thickened papillary dermis (**Fig. 38-11**). Because lesions of mycosis fungoides can become purpuric, it is possible for the lichenoid variants of persistent pigmented purpuric dermatitis to have all the features of purpuric mycosis fungoides except for the striking cytologic atypia or epidermotropism of lymphocytes into the upper spinous layers (in persistent pigmented purpuric dermatitis, lymphocytes can be present within the basal layer but typically do not colonize the upper spinous layers). To the extent that there may be edema of the papillary dermis in persistent pigmented purpuric dermatitis, the conditions can be distinguished histopathologically because the papillary dermis typically is not edematous in mycosis fungoides.

Whether the close histomorphologic similarities between mycosis fungoides and persistent pigmented purpuric dermatitis indicate a biological relationship is an unanswered question. One of the first cases of lichen aureus reported in North America turned out to be mycosis fungoides.[55] Clonality can be present in many cases of persistent pigmented purpuric dermatitis with use of PCR-based methods, making that technique less useful for telling the conditions apart. The clinical picture—whether lesions are mostly on the legs or disseminated—can be more helpful than histopathologic or

immunophenotypic findings. Patients with clinically typical lichen aureus show no significant tendency to progress to mycosis fungoides, despite the finding of clonality detected in PCR-based methods in about half the cases.[56] To our knowledge, at the time of writing this, there are no studies using high-throughput sequencing to evaluate for T-cell clonality in persistent pigmented purpuric dermatitis.

Although children only rarely develop mycosis fungoides, there are several pitfalls in diagnosing such cases. Mycosis fungoides in children seems to result in hypopigmentation in a disproportionate number of cases[57]; so-called “hypopigmented mycosis fungoides” can be mistaken for vitiligo, tinea versicolor, pityriasis alba, and pityriasis lichenoides chronica, and vice versa. Vitiligo usually has symmetrically distributed lesions (unlike those of mycosis fungoides), with a tendency to affect flexural skin. One problem is that biopsy specimens from the edge of the lesion, especially in so-called “trichrome vitiligo,” can feature many lymphocytes among keratinocytes of the basal layer. Biopsy of the center of the lesion should show a picture devoid of lymphocytes and with a lack of melanocytes. Pityriasis alba is a spongiotic dermatitis that results in pale, slightly scaly lesions. There are superficial lymphocytic infiltrates with a touch of spongiosis. The lymphocytes do not align themselves along the junction and are no larger than their dermal counterparts. The dermal papillae should be edematous, not fibrotic. Pityriasis lichenoides chronica is an interface dermatitis, and vacuolar change coupled with single necrotic keratinocytes at the junction should be present along with a broad overlying tier of parakeratosis.

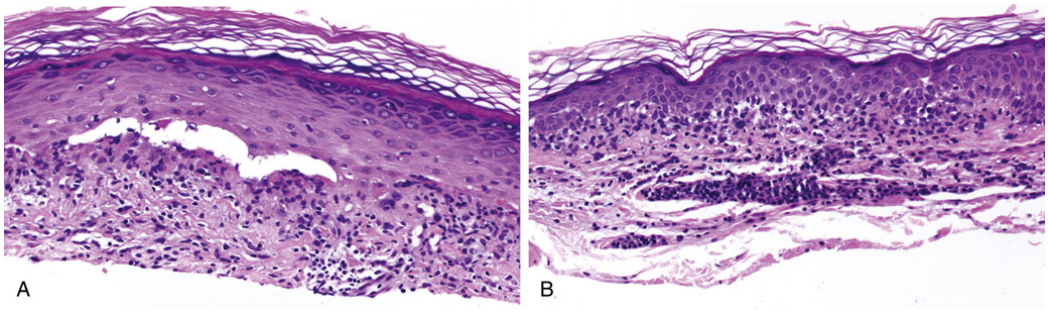

FIGURE 38-10 **A,** The lichenoid variant of mycosis fungoides is easily mistaken for an interface dermatitis. Clefts may be present at the dermoepidermal junction, and there may be wedge-shaped foci of hypergranulosis, as in lichen planus. **B,** Another area features a more characteristic pattern.

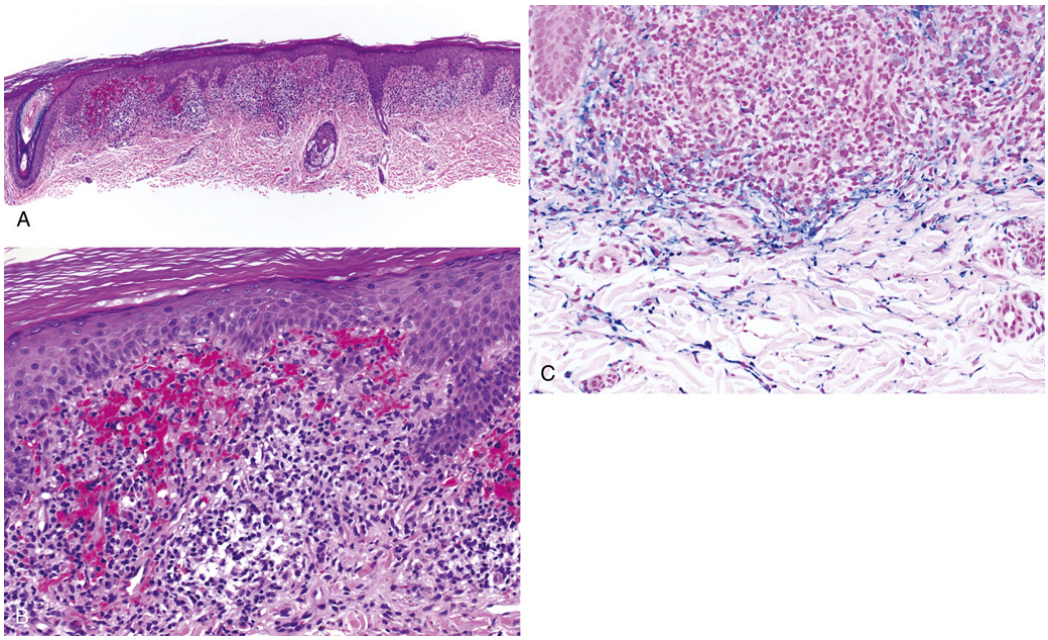

FIGURE 38-11 **A,** Lichenoid purpura can simulate mycosis fungoides because of its psoriasiform lichenoid pattern. **B,** Many extravasated erythrocytes are often present, resulting in the deposition of siderophages. **C,** Siderophages can be highlighted by Perls' stain.

Annular lichenoid dermatitis of youth[58] may simulate mycosis fungoides by virtue of large, annular lesions and a tendency for lymphocytes to be clustered at the bases of rete ridges. The condition, initially reported in children, can also affect young adults. Although the clusters of lymphocytes can resemble those of mycosis fungoides in terms of size, the shape of some of the rete ridges are distinctive. They can be square based in annular lichenoid dermatitis of youth, and the cells in the basal layer are squamous rather than cuboid. In the only large series to date on this condition, clonal T-cell populations were not present. The immunophenotype is usually CD8 positive and cytotoxic.[59]

The atrophic or poikilodermatous patch stage of mycosis fungoides is imitated by several conditions in which the epidermis is thinned by an interface dermatitis (**Fig. 38-12**). These include the atrophic variant of lichen planus (and, rarely, atrophy from a lichenoid drug eruption), poikilodermic dermatomyositis, atrophic centers of lesions of porokeratosis (a condition in which a clone of abnormal keratinocytes migrates centrifugally, sometimes leaving atrophy in its wake), and, occasionally, atrophic lesions of persistent pigmented purpuric dermatitis. There are other rare forms of poikiloderma, such as the congenital Rothmund-Thomson syndrome[60] and dyskeratosis congenita. Similar histopathologic changes also result from regression of melanoma if little pigment is present and from regression of Bowen's disease, superficial basal cell carcinoma, and solar lentigo (so-called "lichen planus–like keratosis"). In all these conditions, and in atrophic patches of mycosis fungoides, lymphocytes of the host response to a neoplasm destroy the keratinocytes of rete ridges, resulting in epidermal atrophy. It may not be possible to distinguish between atrophic mycosis fungoides and these conditions unless many lymphocytes reside in the basal layer of the epidermis. This may require extensive sampling.

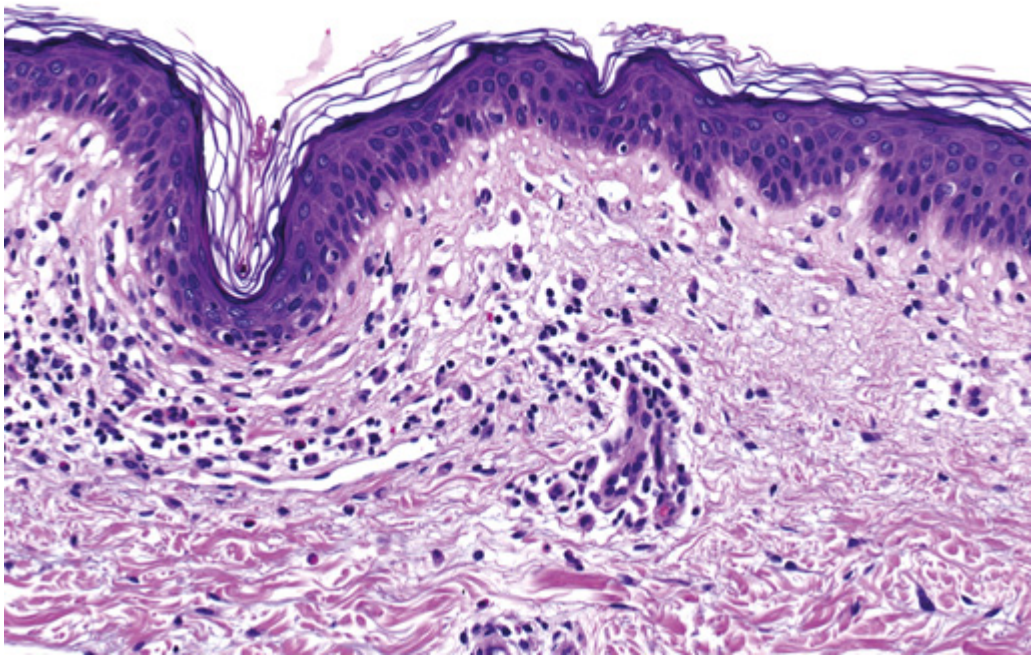

FIGURE 38-12 In the atrophic patch stage of mycosis fungoides, there are often very few lymphocytes within the epidermis, making a specific diagnosis problematic, especially with small biopsy specimens.

Another important mimic of mycosis fungoides is lymphomatoid allergic contact dermatitis.[61] In this unusual type of allergic contact dermatitis, many more lymphocytes are attracted to the epidermis than normally; sometimes the lymphocytes are cytologically atypical. Although a distinction between conventional spongiotic dermatitis and mycosis fungoides is usually possible without recourse to clinical information, in some cases of lymphomatoid contact dermatitis, the clinical history is key.

Drug eruptions can also simulate the patch stage of mycosis fungoides. Diphenylhydantoin can cause a systemic illness in which adenopathy is accompanied by an eruption resembling mycosis

fungoides. This may also occur without any systemic symptoms. The clinical history is one key to making this diagnosis. Other drugs can cause reactions that mimic the patches of mycosis fungoides, even digitate ones.[62] A rash with some clinical and histopathologic similarities to mycosis fungoides can occur in patients treated with mogamulizumab, which is a newer medication that was FDA approved for previously treated advanced-stage mycosis fungoides in 2018. Some potentially helpful discriminatory features that favor a mogamulizumab-associated rash over mycosis fungoides include an inverted or normalized CD4:CD8 ratio and lack of a T-cell clone.[63]

For the most part, the plaque and tumor stages of mycosis fungoides are simulated by other lymphomas, not by inflammatory conditions. One exception is the interstitial type of mycosis fungoides.[64] Interstitial mycosis fungoides usually has scant lymphocytes in the epidermis and papillary dermis in comparison with conventional plaque-stage disease. Its hallmark is the finding of strands of lymphocytes positioned between collagen bundles in the reticular dermis. Clinically, it may resemble some dusky lesions of morphea or granuloma annulare, and it can be very difficult to distinguish it from morphea.

Tumors of mycosis fungoides may be impossible to distinguish from those of other T-cell lymphomas without recourse to clinical examination. The infiltrates of peripheral T-cell lymphomas, not otherwise specified, can present in the skin or with systemic disease.[65] The infiltrates are predominantly dermal. Because some lymphocytes can infiltrate the epidermis in peripheral T-cell lymphomas, a pathologist with no knowledge of the clinical picture cannot differentiate a plaque or tumor of mycosis fungoides from a

nodule of peripheral T-cell lymphoma, not otherwise specified. Only the presence of patches elsewhere on the patient's body allows these conditions to be distinguished. A tumor of mycosis fungoides in which anaplastic large lymphocytes predominate and diffusely express CD30 can be an exact replica of anaplastic large cell lymphoma, but the patient has a much worse prognosis. Again, the clinical examination is key.

In some cases, CD4-positive small-to-medium-sized T-cell lymphoproliferative disorder can be particularly problematic to distinguish pathologically from tumor-stage mycosis fungoides. Usually, very few lymphocytes are present in the epidermis. Therefore, the differential diagnosis is a tumor of mycosis fungoides with little epidermal involvement and a predominance of smaller cells. The number of B cells in this condition is substantial and has been attributed to a proliferation of T follicular helper cells.[66-68] Primary cutaneous CD4-positive small-to-medium-sized T-cell lymphoproliferative disorder usually presents as a single plaque or nodule, whereas mycosis fungoides presents with multiple lesions. Therefore, it is imperative to perform a full-body skin examination to assess for clinical evidence of mycosis fungoides before making the diagnosis of CD4-positive small-to-medium-sized T-cell lymphoproliferative disorder. For this reason, we typically render descriptive reports for this condition and include a note that a full-body skin examination needs to be done to assess for mycosis fungoides before an unequivocal diagnosis can be rendered. The prognosis is excellent compared with that of tumor-stage mycosis fungoides.

Variants

The various effects of the cells of mycosis fungoides on the different constituents of the skin, the effects of host inflammatory cells responding to the neoplastic ones, and the disturbed microenvironment of cytokines, chemokines, and the like account for the prodigious differences in the clinical and microscopic appearance of mycosis fungoides lesions. The cells of mycosis fungoides, which are usually home to the epidermis, can also localize in other sites.

Folliculotropic Mycosis Fungoides

The hair follicles can become a magnet for the cells of mycosis fungoides (**Fig. 38-13A**). On histopathologic evaluation, lesions of folliculotropic mycosis fungoides feature variably dense perifollicular infiltrates of lymphocytes and, notably, eosinophils; lymphocytes within the follicular epithelium; and plugging of follicular ostia by compact hyperkeratosis. The interfollicular epidermis is often spared, and most of the lymphocytes are relatively small, making an outright diagnosis of lymphoma difficult. This reaction is sometimes although not always accompanied by the accumulation of mucopolysaccharides between keratinocytes in the outer root sheath (**Fig. 38-13B**). The result is the distention of intercellular spaces in the outer root sheath. In well-balanced hematoxylin-eosin–stained sections, the mucin can be detected as tiny basophilic granules. Keratinocytes adjacent to the widened spaces are often elongated, and the spines connecting them appear stretched. In some cases, lymphocytes do not infiltrate the epithelium and are not sufficiently atypical to establish a diagnosis of mycosis fungoides on cytologic grounds alone. Nonetheless, a widespread eruption composed of

folliculocentric plaques is probably best classified as folliculotropic mycosis fungoides.

Clinically, this variant presents with a different distribution compared with conventional mycosis fungoides because lesions are typically on the head, neck, and upper trunk rather than on the double-clothed areas. The clinical lesions are often erythematous patches and plaques with follicular prominence that are markedly pruritic and frequently are associated with hair loss. Small follicular-based papules can occur as well. These follicular papules can clinically simulate keratosis pilaris or other follicular diseases, such as follicular lichen planus. Although early studies suggested that these patients have a less favorable prognosis than those with conventional mycosis fungoides,[69-71] later series have demonstrated that prognosis is not as poor as the earlier studies suggested.[72]

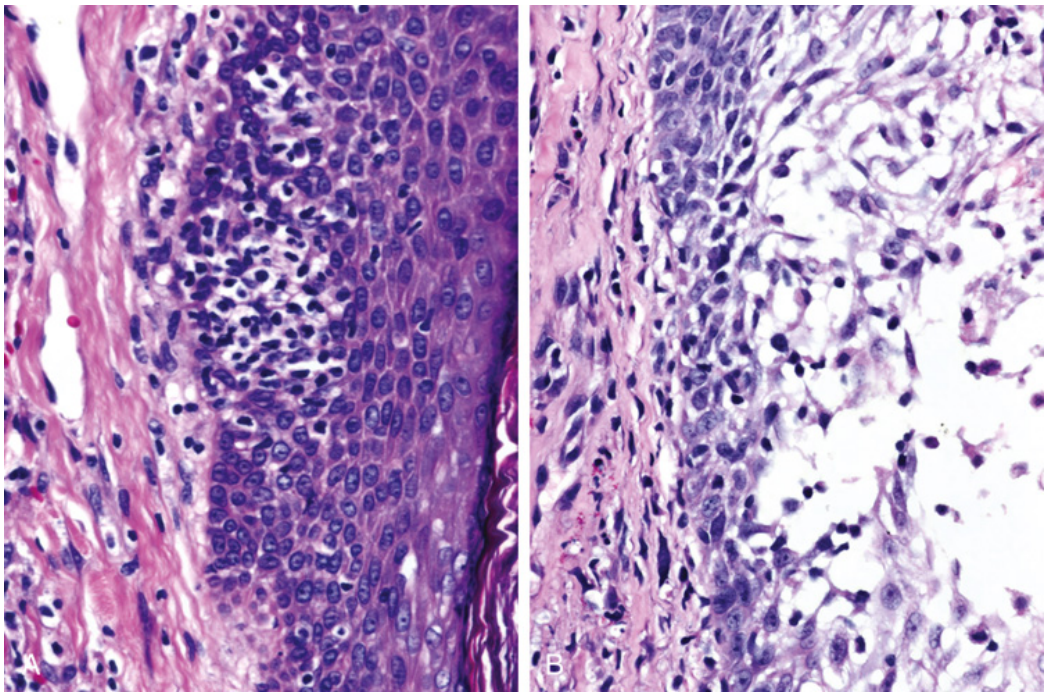

FIGURE 38-13 **A,** In folliculotropic mycosis fungoides, lymphocytes may home to the follicular epithelium rather than to the epidermis. **B,** In some cases of folliculotropic mycosis fungoides, spaces between keratinocytes are markedly widened because of the accumulation of mucin.

Although it was mentioned earlier that mucin can be present within the affected follicles, it should be noted that mucin within follicles is not specific for folliculotropic mycosis fungoides and can occur as an incidental finding, in conventional lesions of mycosis fungoides (usually in plaques or tumors) or in a condition termed *alopecia mucinosa*. *Alopecia mucinosa* is a term initially coined to refer to a condition thought to be an inflammatory reaction (i.e., not a lymphoma) in which plaques of alopecia are present on the hair-bearing skin of young persons, with mucin accumulating in the

affected follicles. Some studies suggest that the distinction between alopecia mucinosa and folliculotropic mycosis fungoides may not be valid and that alopecia mucinosa may in fact be an indolent form of mycosis fungoides.[73,74] Further, studies of T-cell receptor gene rearrangements have found clonal populations in about the same number of cases of both idiopathic alopecia mucinosa and mycosis fungoides with follicular mucinosis. Nevertheless, the relationship between alopecia mucinosa and mycosis fungoides remains an area of debate.

Mycosis Fungoides With Cysts and Comedones

Some patients with follicular mycosis fungoides, with or without follicular mucinosis, have lesions in which large comedones or even follicular cysts develop.[75,76] This probably results from occlusion of the follicular infundibulum by the infiltrates of mycosis fungoides. This complication is disfiguring but may respond to treatment of the disease. The prognosis is the same as that for follicular mycosis fungoides.

Bullous Mycosis Fungoides

In this rare variant, the cells of mycosis fungoides replace basal keratinocytes to the extent that cohesion between the epidermis and dermis is compromised, and trivial shearing forces result in clinical vesiculation. The diagnosis can usually be made by examining areas that have not vesiculated.[77]

Syringotropic Mycosis Fungoides

Lymphoma cells' tropism for secretory glands is exemplified by the lymphoepithelial lesions formed in some low-grade B-cell

lymphomas, such as extranodal marginal zone lymphomas (although not in the skin). Some patients with mycosis fungoides have dense infiltrates of lymphocytes around eccrine secretory coils in addition to infiltrates elsewhere in the dermis and epidermis (**Fig. 38-14**).[78,79] A more purely syringotropic variant of mycosis fungoides in a patient who also had folliculotropic infiltrates was initially described as *syringolymphoid hyperplasia with alopecia*.[80] The cutaneous lesions are often small papules and may be accompanied by anhidrosis. Most authors accept that this condition is a variant of mycosis fungoides rather than an inflammatory disease.[81] This variant is too rare to know with certainty whether its prognosis is different from that of more common forms, but in a review of 15 cases published before 2004, its behavior seemed unremarkable.[82]

Pagetoid Reticulosis

In contrast to the bullous and syringotropic variants, which have lymphocytes that ignore the epidermis in favor of adnexal epithelium, the lymphocytes' attraction to the epidermis is exaggerated in pagetoid reticulosis. The affected skin is usually on the extremities, so the clinical lesions are warty, hyperkeratotic plaques on the hands and feet (**Fig. 38-15**). Pagetoid reticulosis was initially described by Woringer and Kolopp in two children; subsequent reports have highlighted that it occurs in younger patients than is usual for mycosis fungoides. It also differs from conventional mycosis fungoides by its failure to disseminate in most cases as it usually presents as a solitary plaque.

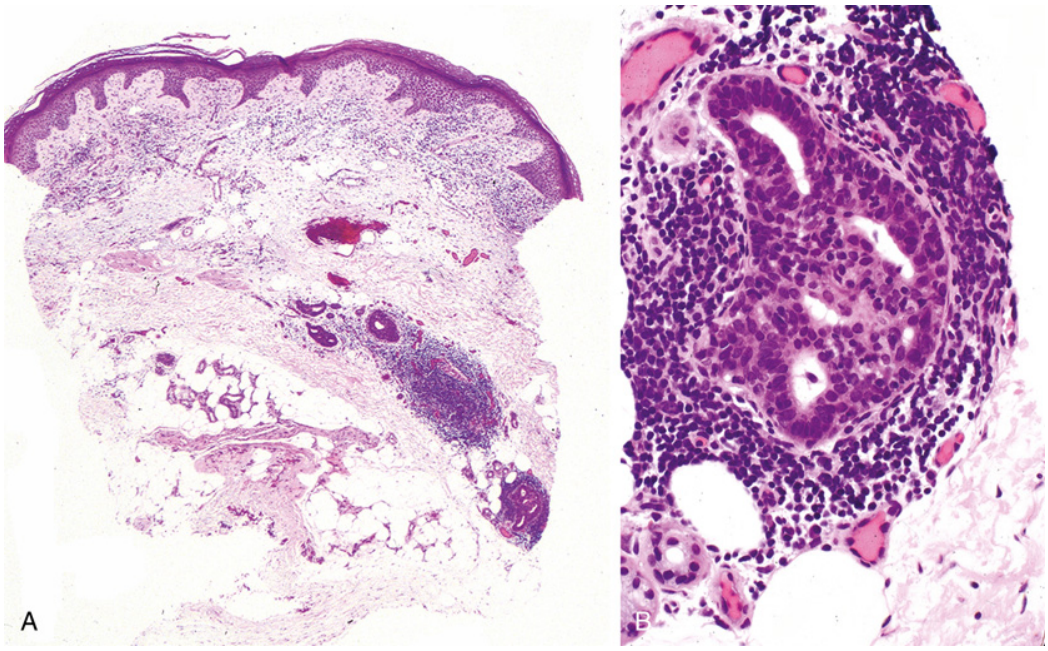

FIGURE 38-14 **A,** Syringotropic mycosis fungoides features dense infiltrates of lymphocytes around the eccrine secretory coils. **B,** There may be hyperplasia of the epithelial cells, similar to that in lymphoepithelial lesions.

FIGURE 38-15 Woringer-Kolopp disease, or pagetoid reticulosis, presents as verrucous plaques on acral skin. Courtesy Dr. Sabine Kohler, Stanford University.

Its histopathologic hallmark is verrucous epidermal hyperplasia, coupled with infiltrates of lymphocytes that have cytologic atypia and are disproportionately situated in the epidermis (**Fig. 38-16**).[83] The immunophenotype includes CD4-positive or CD8-positive T cells. Compared with conventional mycosis fungoides, pagetoid reticulosis has a greater propensity to be CD30 positive, although most cases will not label with CD30. In addition, some cases of pagetoid reticulosis lack CD45 expression (leukocyte common antigen).[84] Its prognosis is far better than that of conventional mycosis fungoides. Many patients achieve durable remissions by local therapeutic means, such as excision of lesions or radiation therapy.

Another entity that shares the moniker pagetoid reticulosis is the Ketron-Goodman variant of mycosis fungoides, with striking epidermotropism and disseminated lesions. Some examples of this condition have a CD4-negative, CD8-negative (double negative) phenotype.[85] Most of these cases have now been reclassified as primary cutaneous CD8-positive aggressive epidermotropic T-cell lymphoma, sometimes termed *Berti's lymphoma*.[86]

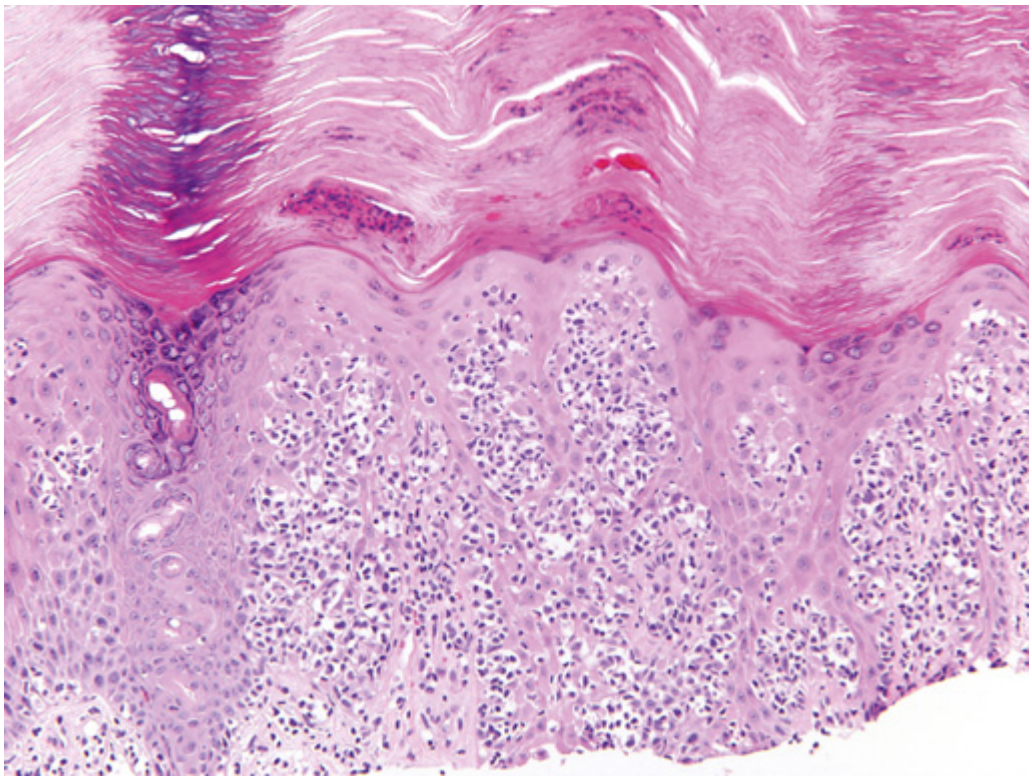

FIGURE 38-16 Histopathologic findings in pagetoid reticulosis include verrucous epidermal hyperplasia with infiltration of the epidermis, similar to or even more pronounced than that seen in conventional mycosis fungoides.

Solitary Mycosis Fungoides

Whereas pagetoid reticulosis represents a solitary variant of mycosis fungoides that usually develops on acral skin, mycosis fungoides can occasionally present as a solitary lesion in the typical distribution of mycosis fungoides (i.e., the double-clothed areas).[87] Such cases are best regarded as a solitary variant of mycosis fungoides. Most reports have not demonstrated development of more widespread lesions in such patients.[88] Of note, folliculotropic mycosis fungoides can present with a solitary lesion as well.[89]

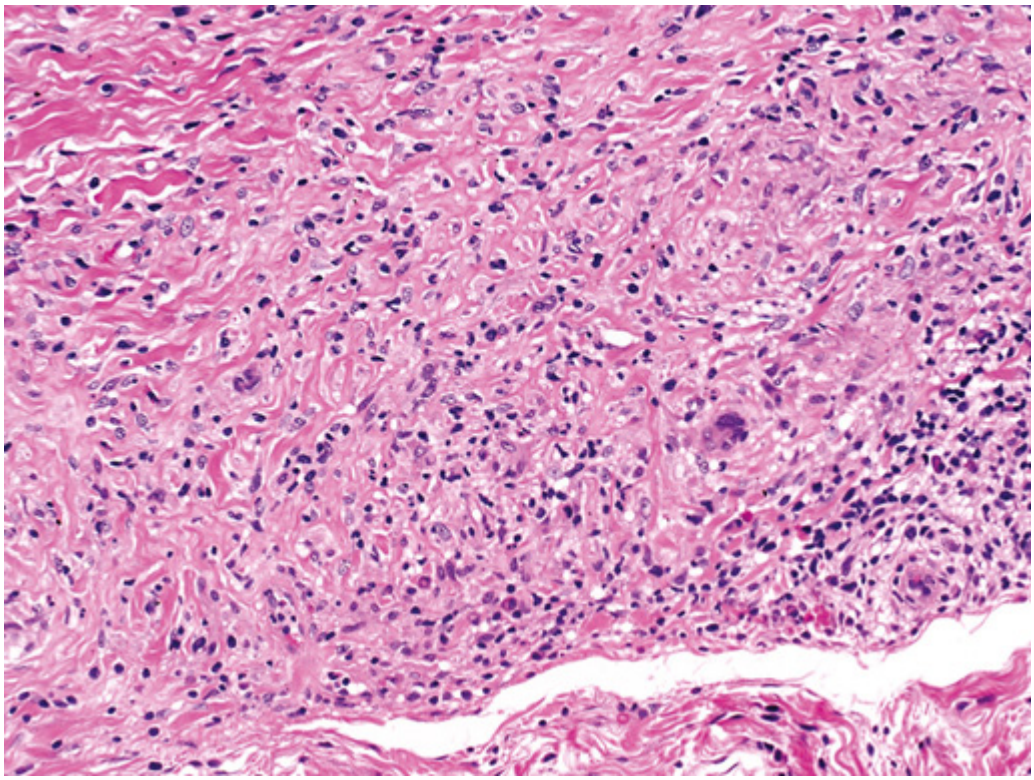

FIGURE 38-17 Granulomatous mycosis fungoides is not distinctive clinically, but its histopathologic findings include many histiocytes, sometimes multinucleated, interspersed with lymphocytic infiltrates in the dermis.

Granulomatous Mycosis Fungoides

There are many lymphomas, both cutaneous and nodal, that have foci in which histiocytes predominate. Plaques and tumors of mycosis fungoides can contain such foci in the reticular dermis. The findings can range from loose clusters of histiocytes to scattered giant cells to well-formed granulomatous tubercles (**Fig. 38-17**). The plaques and tumors of granulomatous mycosis fungoides usually do not have a distinct appearance.

In the initial description of granulomatous mycosis fungoides, the authors noted that their patient had survived longer than expected. Fourteen years later, their patient was still alive and had had granulomatous mycosis fungoides for nearly 3 decades.[90] Their conclusion, that the prognosis of granulomatous mycosis fungoides is more favorable than that of conventional mycosis fungoides, has not been confirmed by other studies.[91,92] There may be a variety of causes of granulomatous infiltrates in mycosis fungoides: lymphocytes may attract histiocytes, giant cells may be moved to phagocytize elastotic fibers (similar to the foci that resemble actinic granuloma in many inflammatory diseases in sun-damaged skin), or keratin or mucin from leaky follicles may incite a granulomatous reaction. A reanalysis of the data seems to be prudent before firm conclusions are reached about the prognosis of this variant.

Granulomatous Slack Skin

Granulomatous slack skin is a peculiar condition in which the cells of an epidermotropic T-cell lymphoma attract histiocytes, which in turn digest elastic tissue and lead to the formation of large saclike skin folds. The disease affects younger patients than is usual for mycosis fungoides, with most cases beginning in young adulthood. The usual sites of involvement are the axilla and groin (**Fig. 38-18**). Hodgkin lymphoma has reportedly developed in several patients with granulomatous slack skin.[93,94] However, it is uncertain whether the lymphoma that develops in the internal organs of patients with granulomatous slack skin is truly Hodgkin lymphoma or a large T-cell lymphoma, given that the reported cases were not comprehensively worked up by current standards. In a retrospective

multicenter study of patients with granulomatous slack skin, 25% were associated with visceral involvement.[95]

FIGURE 38-18 Granulomatous slack skin typically presents with pendulous masses in the axilla and groin.

The most striking histopathologic feature of granulomatous slack skin is involvement of the dermis and subcutaneous lobules by tuberculoid granulomas—clusters of histiocytes and giant cells surrounded and infiltrated by small lymphocytes.[96-98] The tubercles tend to be discrete and spaced at regular intervals throughout the infiltrate (**Fig. 38-19**). The giant cells sometimes contain elastic fibers as seen in specially stained sections, indicating that they are responsible for the profound elastolysis that occurs in this condition and leads to the distinctive pendulous skin folds.

Only when one examines the epidermis and papillary dermis is it evident that granulomatous slack skin is related to mycosis fungoides. Indeed, the changes in the superficial part of the biopsy specimen can be identical to those of mycosis fungoides. Immunophenotypic studies have been performed in only a few cases, but they indicate a CD4-positive, CD7-negative T-cell population, like that of mycosis fungoides. Gene rearrangement studies have shown clonality in almost all cases tested to date.

Sézary Syndrome

Definition

The classic features of Sézary syndrome include Sézary cells in the peripheral blood (lymphocytes with abnormally convoluted nuclei; **Fig. 38-20**), erythroderma (diffuse reddening of the skin; **Fig. 38-21**), and lymphadenopathy.

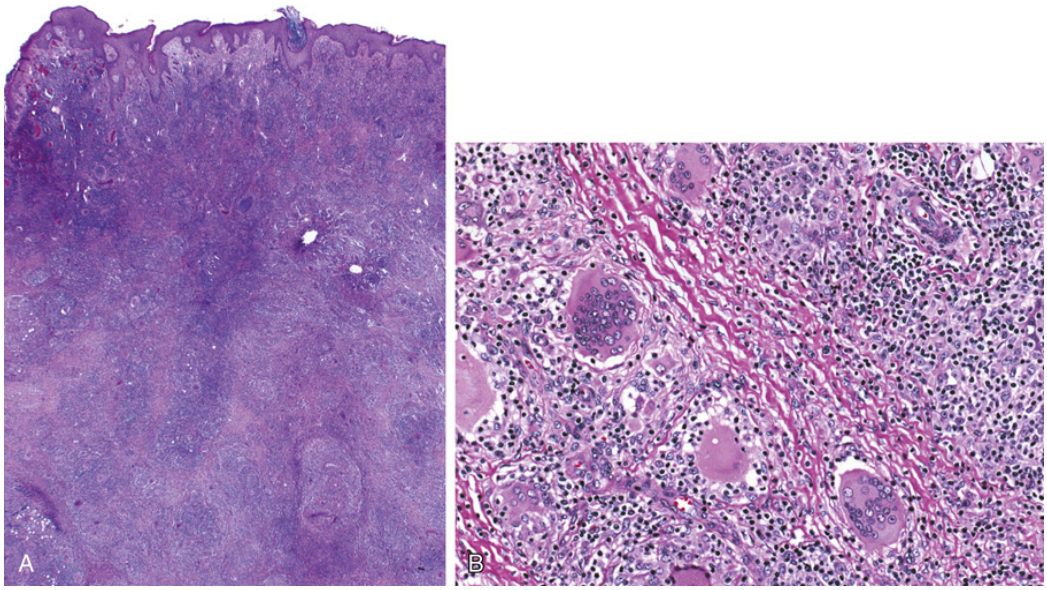

FIGURE 38-19 Granulomatous slack skin usually shows a dense, diffuse infiltrate of small lymphocytes throughout the dermis **(A)**, with infiltration of the epidermis similar to that seen in mycosis fungoides and large histiocytic giant cells that exhibit elastophagocytosis **(B)**.

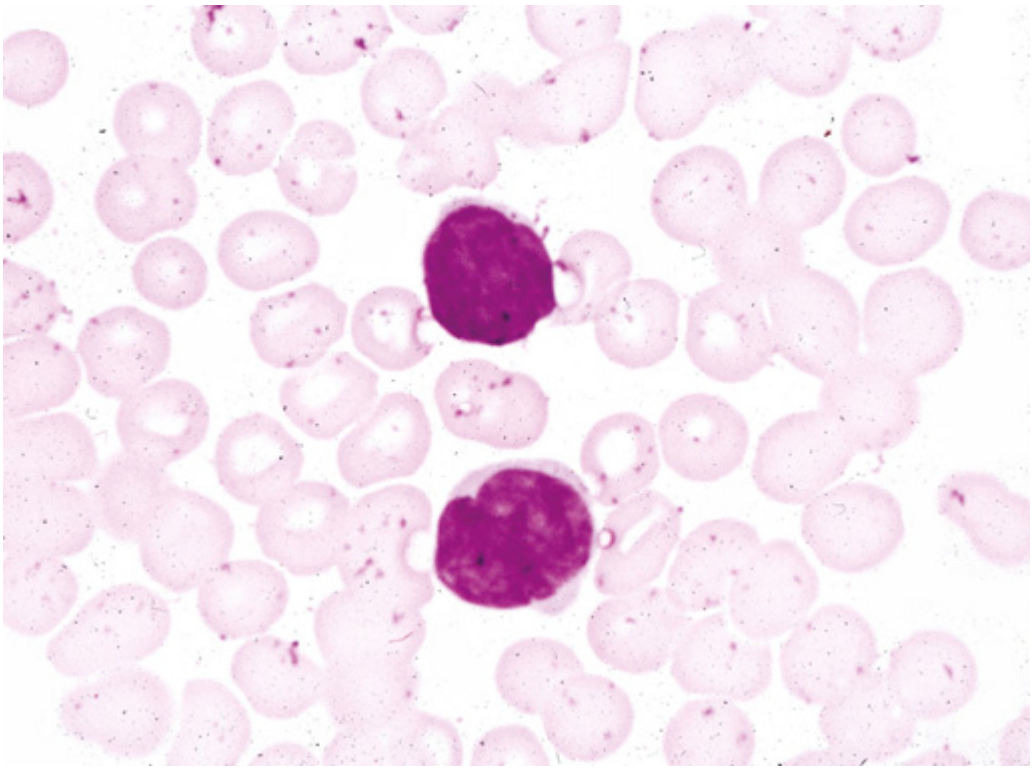

FIGURE 38-20 Sézary cells in a peripheral blood smear. Recognition of these cells is no longer critical for the diagnosis since the advent of clonality studies and flow cytometry.

Whereas light microscopic evaluation of peripheral blood was used in the past to assess for the presence of Sézary cells in the peripheral blood, studies have since demonstrated limitations to this method. In particular, a small cell variant of the Sézary cell was described that would not have been detected on a peripheral smear.[99] Furthermore, normal resting lymphocytes were demonstrated to be able to acquire a Sézary cell phenotype under experimental conditions.[100] Finally, on occasion, morphologically similar lymphocytes could be detected in benign dermatoses.[101] For these reasons, alternative methods to assess blood involvement in patients with possible Sézary syndrome are now used at most medical centers. In particular, a combination of

flow cytometry with genotypic analysis is used in most centers to assess for the presence of Sézary cells in the blood, and criteria that need to be met to render a diagnosis of Sézary syndrome in the blood have been published. Specifically, these criteria state that there needs to be a T-cell clone in the blood along with flow cytometry showing either a CD4/CD8 ratio of more than 10:1 or loss of either CD7 on more than 40% of the CD4-positive cells or loss of CD26 on more than 30% of the CD4-positive cells.[102] Criteria for "high blood tumor burden" in mycosis fungoides or Sézary Syndrome (B2 in the revised classification of the International Society for Cutaneous Lymphomas and European Organisation of Research and Treatment of Cancer) include finding clonal rearrangement of the TCR in the blood and either 1.0 K/L or more Sézary cells or one of the two following criteria: (1) increased CD4-positive or CD3-positive cells with a CD4/CD8 ratio of 10 or more or (2) increase in CD4-positive cells with an abnormal phenotype (≥40% CD4 positive/CD7 negative or ≥30% CD4 positive/CD26 negative.[102] The major diagnostic features of Sézary syndrome are listed in **Box 38-3**.

FIGURE 38-21 Sézary syndrome presents with erythroderma—diffuse red skin. The term *erythroderma* is often overused by clinicians; it should refer to confluent erythema, not just widespread erythematous lesions.

Epidemiology

Like mycosis fungoides, Sézary syndrome is a disease of the middle-aged and elderly, although we have seen occasional cases in younger patients in their early 20s at our center. When strictly defined—requiring true erythroderma rather than just disseminated lesions—it is much less common than mycosis fungoides.

Etiology

There are no widely accepted risk factors for Sézary syndrome. The high level of UV signature mutations in about one-quarter of cases raises the possibility that this exposure could be causative in some patients.[103]

Immunophenotype

The majority of cases of Sézary syndrome are CD3+, CD4+, CD8−, CD7−, CD26− neoplasms consisting of mature helper T cells, similar in these respects to mycosis fungoides. Using the numerical assessments for CD4/CD8, CD4-positive/CD7-negative, and CD4-positive/CD26-negative T cells noted, flow cytometry can be helpful in making the diagnosis of Sézary syndrome from peripheral blood in the presence of the other diagnostic criteria. This phenotypic profile, however, does not exclude a benign disorder, leading to recommended additional phenotypic analyses, such as a more complete analysis looking for other immunophenotypic aberrancies and TRBC1 analysis on T-cell subsets.[104-106] As with mycosis fungoides, the neoplastic cells in Sézary syndrome may also express T follicular helper cell antigens.[36,37] One must also remember that in skin biopsy specimens, an elevated CD4/CD8 ratio is not as specific.[107] The phenotype in a given patient is sufficiently stable that flow cytometry can be used to monitor response to therapy.[108] However, while one or more aberrancies may remain stable, phenotypic variation does occur over time in a subset of patients, so caution is advised.[103]

Genotypic Features

Sézary syndrome has long been known to be a clonal T-cell proliferation.[109] Because a clonal population of T cells cannot be detected in a subset of skin biopsy specimens from patients with Sézary syndrome, and because a clonal population of T cells is present in the blood by definition in Sézary syndrome, the detection of a clonal population of T cells in the blood rather than in the skin can be used to prove clonality in Sézary syndrome. Some criteria do require clonally related neoplastic cells in skin, lymph node, and blood, although this is not a standard part of the required workup. Chromosomal abnormalities, including complex numerical and structural alterations and with recurrent copy number alterations, can be identified in Sézary syndrome, but no one abnormality is found in a preponderance of cases.[110] They do highlight the genomic instability in this neoplasm. Next-generation sequencing have revealed frequent mutations in elements of the JAK-STAT *(JAK3, STAT3)* and TCR signaling *(PLCG1, CD28, TNFR1F1B)* pathways, *RHOA, TP53,* and in epigenetic regulators. Some of these alterations are also present in mycosis fungoides.[111-114] The molecular/cytogenetic abnormalities in Sézary syndrome have been recently reviewed.[42]

Box 38-3 Key Diagnostic Features of Sézary Syndrome

Clinical Features

- Erythroderma caused by atypical lymphocytes in the skin
- Atypical lymphocytes in blood

- Atypical lymphocytes in lymph nodes

Histopathologic Features

- Dense bandlike infiltrate of lymphocytes in the upper dermis, sometimes with lymphocytes in the epidermis (i.e., epidermotropism)
- In some cases, some of the lymphocytes might have somewhat large and hyperchromatic nuclei

Immunohistochemical Features

- βF1-positive, CD3-positive, CD4-positive, CD8-negative immunophenotype

Genotypic Findings

- Demonstrable clonality common but not obligatory by polymerase chain reaction (PCR)–based gamma alone or gamma plus beta chain gene rearrangements

Postulated Cell of Origin

Sézary syndrome appears to be a malignant disease of central memory CD4-positive T cells based on their expression of CCR7, L-selectin, and CD27.[115]

Clinical Features

The salient clinical features of Sézary syndrome—erythroderma, palmar and plantar hyperkeratosis, and lymphadenopathy—were

first noted by Sézary and Bouvrain in their original report (**Fig. 38-21**). Erythroderma is a clinical sign in which the entire skin becomes red and sometimes scaly. It has also been called the "red man" effect. In erythroderma caused by lymphoma, the skin can become doughy as well in some cases, but not in all. There are many other causes of erythroderma besides Sézary syndrome, but its presence in a middle-aged or older patient should evoke a differential diagnosis that includes lymphoma. Hyperkeratosis of the palms and soles leads to red, scaly, and sometimes fissured skin. The nails may be lost or become dystrophic. Generalized lymphadenopathy is often present in patients with Sézary syndrome. The 5-year disease specific survival in Sézary syndrome is reported at 36%.[115a]

Histopathology

Diagnostic biopsy specimens of Sézary syndrome show identical features to definitive biopsy specimens of late patch-stage or plaque-stage mycosis fungoides. In particular, there is usually a dense bandlike infiltrate of lymphocytes, some of which exhibit epidermotropism. Some of the lesional lymphocytes can be large, although the cells will not appear atypical in some cases. Nonetheless, performing skin biopsies as a method to diagnose Sézary syndrome can be a frustrating exercise because spongiosis can be the predominant finding and epidermotropism may be absent (**Fig. 38-22**). In fact, one study showed that diagnostic findings of Sézary syndrome are present in 60% of cases.[116] Therefore, the lack of a diagnostic biopsy does not exclude Sézary syndrome. As such, if Sézary syndrome is a serious clinical consideration, evaluation of the peripheral blood for the presence of a clone or an abnormal

immunophenotype as assessed by flow cytometry should be performed. If these tests show findings that meet the criteria for diagnosis, the patient should be classified as having Sézary syndrome with nondiagnostic skin biopsies.

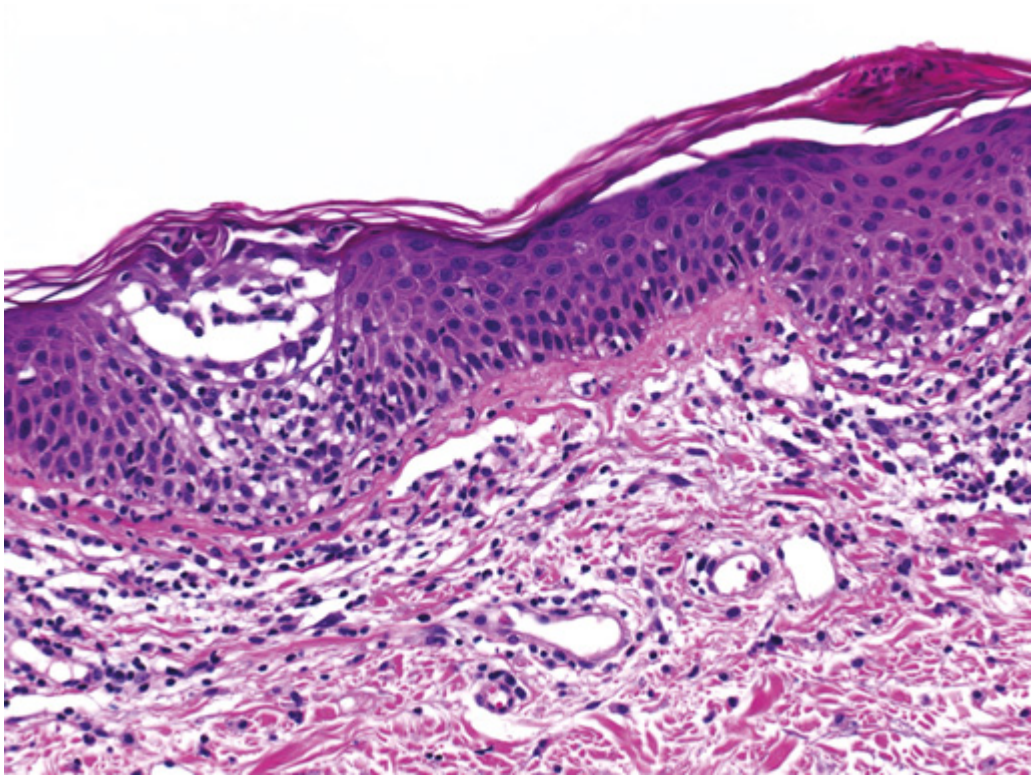

FIGURE 38-22 The histopathologic findings in Sézary syndrome often fall short of being diagnostic. In this example, there is too much spongiosis for an outright diagnosis without knowing the clinical and peripheral blood findings.

Differential Diagnosis

Because of the many inflammatory conditions that cause erythroderma and because of the lack of diagnostic changes in the biopsy specimens of many patients with Sézary syndrome, one must approach the differential diagnosis of erythroderma with great caution. The most common causes of erythroderma include psoriasis, pityriasis rubra pilaris, generalized allergic contact dermatitis, and drug eruptions. In some patients the erythroderma resolves spontaneously, and its cause is never determined. In general, the histopathologic features of erythrodermic presentations of inflammatory skin diseases are those of the underlying condition.

The findings in erythrodermic psoriasis resemble those of early patches of psoriasis rather than well-developed plaques. The rete ridges are slightly elongated; keratinocytes have pale cytoplasm; and dilated, tortuous vessels are prominent in edematous dermal papillae and may even appear to touch the undersurface of the epidermis. Small mounds of parakeratosis, both with and without neutrophils, may be present.

Pityriasis rubra pilaris shares many features with psoriasis, but it presents with diffuse orange-red skin. The palms and soles of affected patients are often thickened by cornified material that has been likened to carnauba wax. Biopsy specimens of pityriasis rubra pilaris often show slight psoriasiform epidermal hyperplasia, an epidermis with a gently undulating surface, and lamellar hyperkeratosis containing scattered parakeratotic nuclei.

Erythrodermic allergic contact dermatitis represents a generalized response to a contactant. Its features are essentially those of a conventional spongiotic dermatitis. There may be more of a tendency

for the inflammatory cells in the papillary dermis to have a bandlike pattern than in conventional allergic contact dermatitis.

Erythrodermic drug eruptions have a variety of histopathologic presentations. These include the findings of spongiotic dermatitis, interface dermatitis, and, rarely, psoriasiform dermatitis.

Pearls and Pitfalls

Diagnosing Early Mycosis Fungoides

- Diagnosis during the patch stage is optimal but may not influence survival.
- Overdiagnosis of mycosis fungoides can be emotionally traumatic to patients.
- Immunophenotypic studies are usually not essential for diagnosis and do not provide prognostic information.
- Genotypic studies are useful for confirming the diagnosis only if mycosis fungoides is clinically and pathologically plausible. T-cell clonality is not equivalent to the diagnosis of a lymphoid neoplasm.
- There are myriad inflammatory skin diseases, and many can simulate mycosis fungoides clinically and pathologically. The diagnosis of mycosis fungoides is best established with the collaboration of a knowledgeable clinician, unless the histopathologic findings are unequivocal.

Definition

Primary cutaneous CD30-positive T-cell lymphoproliferative disorders (CD30+ LPDs) are the second-most-common form of cutaneous T-cell lymphoma (CTCL), accounting for 25% to 30% of CTCLs. Three types of CD30+ LPDs are recognized in the 4th, revised 4th, and proposed 5th editions of the World Health Organization (WHO) classification, the WHO-EORTC classification, and the 2022 International Consensus Classification (ICC): primary cutaneous anaplastic large cell lymphoma (C-ALCL), lymphomatoid papulosis (LyP), and borderline lesions. These entities represent a continuous spectrum with overlapping clinical and histopathological features (**Table 39-1**).[1-3]

LyP is defined by multiple recurrent, papulonodular lesions up to 2 cm in diameter that may become centrally necrotic and may ulcerate.[4] The individual lesions regress spontaneously, usually in 4 to 6 weeks, occasionally leaving a hyperpigmented or hypopigmented scar.[5,6] C-ALCL commonly presents as one to several tumors greater than 2 cm in diameter and is often solitary or localized, but can present with multifocal lesions in some cases.[4,6] The tumors of primary C-ALCL frequently ulcerate. Partial or complete regression of tumors occurs at diagnosis or relapse in up to 42% of patients.[7] Occasionally LyP and C-ALCL cannot be distinguished even by a clinicopathologic correlation. For these lesions, the term *borderline lesion* can be used. Borderline lesions are intermediate in size, clinical appearance, and histology and usually persist for several months if not treated (**Fig. 39-1**).[8]

Primary cutaneous CD30-positive T-cell LPDs present in the skin without extranodal manifestations at the time of diagnosis.[4,7] Primary cutaneous CD30-positive T-cell LPDs must be distinguished from secondary cutaneous manifestations of systemic ALCLs and from other CTCLs such as mycosis fungoides (MF) or Sézary syndrome (SS) that may show expression of CD30 by tumor cells, usually in advanced disease. Secondary CD30-positive cutaneous lesions generally have a worse prognosis than primary cutaneous CD30+ LPDs.[7,9]

SYNONYMS AND RELATED TERMS

Lymphomatoid papulosis
Cutaneous anaplastic large cell lymphoma

Epidemiology

LyP has an incidence of 1.2 to 1.9 cases per 1,000,000 people.[7,10-12] The peak incidence is in the 4th and 5th decades (median age 35–45 years), although children younger than 10 years and patients up to 80 years old can be affected.[13,14] The male-to-female ratio for LyP patients from 10 published series is 1.5:1.[7,10-12,15,16]

For primary C-ALCL, the male-to-female ratio is 2.5:1.[7] Primary C-ALCL can occur in children; importantly, not all cases of C-ALCL in children should be considered secondary manifestations of systemic ALCL. Lack of anaplastic lymphoma kinase (ALK) expression favors primary C-ALCL.

The LyP registry data at Beth Israel Deaconess Medical Center in Boston revealed an interesting bimodal distribution of patients at age of diagnosis. Most patients younger than 19 years were male, and most of those aged 19 or older at diagnosis were female. Two-thirds of 35 patients who developed LyP in childhood (younger than 18 years) had atopy, which is significantly more than the expected prevalence (relative risk, 3.1; 95% confidence interval [CI], 2.2–4.3).[14] Fletcher et al. reported four cases of primary cutaneous CD30+ LPDs (one LyP, three C-ALCLs) in young adult patients with active atopic eczema since early childhood.[17] These results from separate medical centers suggest an association between primary cutaneous CD30+ LPDs and atopy.[18]

FIGURE 39-1 Clinical appearance of skin lesions in CD30-positive cutaneous lymphoproliferative diseases.**A,** Clustered lesions of lymphomatoid papulosis (LyP) with necrotic centers in various stages of spontaneous regression. **B,** Eschar as a result of angioinvasive LyP type E. **C,** Coexistent lesions of LyP and patch-stage mycosis fungoides. **D,** Coalescence of multiple separate lesions to form a cutaneous anaplastic large cell lymphoma (C-ALCL). **E,**

Multiple clustered tumors of C-ALCL. **F,** Borderline lesion of intermediate appearance. No regression was observed.

A remarkable association between LyP and other lymphomas occurs in 10% up to 62% of patients (for details see Kempf et al. 2014).[19] The most common lymphomas are MF, Hodgkin lymphoma (HL), and ALCL.[7,10,12,15,16,20-26] In addition, the incidence of non-hematologic neoplasms such as breast cancer seems also to be increased in patients with LyP.[22,26] A case-control study revealed that of 57 LyP patients, 3 had HL, 3 had non-HL, 10 had MF, and 4 had nonlymphoid malignancies (1 brain tumor, 2 lung cancers, 1 breast cancer).[15] In addition, four patients had received radiation therapy 8 to 40 years before the onset of LyP. None of 67 age-and-gender-matched controls had any history of radiation or lymphoid or nonlymphoid malignancy. A Dutch study of 118 LyP patients found that 23 (19%) had lymphomas (11 MF, 10 C-ALCL, 2 HL).[7] In addition to lymphomas, prospective follow-up of our 57 LyP case-control patients revealed a high frequency of nonlymphoid malignancies (10 of 57; 18%). The relative risk of developing lymphoid and nonlymphoid malignancies in this cohort of patients over 8.5 years of follow-up was 13 (95% CI, 2.2–44) and 3.1 (95% CI, 1.206–6.47), respectively.[22] The factors that predispose these patients to develop malignancies are unknown. Possible risk factors based mostly on small case series include age at onset, male gender, histologic subtype, and expression of fascin by CD30-positive cells in LyP.[12,14,27-29] For example, Dutch investigators found that patients with type C LyP have an increased risk of developing malignant lymphoma, whereas none of seven patients with pure type B lesions

had or developed a malignant lymphoma.[27] Clinical manifestations of MF or HL can occur before, after, or simultaneously with LyP. In nearly all cases, LyP lesions precede the development of C-ALCL.[27]

Table 39-1

C-ALCL, Cutaneous anaplastic large cell lymphoma; *LCA,* leukocyte common antigen; *LyP,* lymphomatoid papulosis; *PMN,* polymorphonuclear leukocyte; *RS,* Reed-Sternberg; *TCR,* T-cell receptor.

* As an exception, a very small subset of C-ALCL carries t(2;5)(p23;q35) and expresses ALK, but shows a similar biological behavior as ALK-negative C-ALCL.

Etiology

The etiology of LyP and C-ALCL is unknown. A viral origin was initially suspected but has not been confirmed.[30-32] Human T-lymphotropic virus 1 (HTLV-1), herpesviruses 6, 7, and 8, and Epstein-Barr virus (EBV) could not be detected in primary skin lesions or in cell lines derived from CD30-positive cutaneous lymphomas.[33-35] Interestingly, sequences of endogenous retroviral elements were identified, but their role still needs to be elucidated.[35]

CD30 expression is a hallmark of LyP and C-ALCL.[36-38] CD30 is a "late" activation antigen maximally expressed 72 hours after lymphocyte activation in vitro.[39] Engagement of CD30 by its natural ligand CD30L (CD156) can lead to sustained proliferation, cell cycle arrest, or apoptosis, depending on the target cell, its state of differentiation, and environmental costimulatory signals.[40-43] CD30

cross-linking of ALCL cell lines clonally derived from LyP causes upregulation of nuclear factor-κB (NF-κB) and ERK/MAP kinases, promoting cell survival and proliferation.[42] CD30 activation also enhances expression of FLICE-like inhibitory protein, which protects lymphocytes from apoptosis induced by Fas/CD95.[44] Our studies suggest that the level of CD30 transcription is genetically determined, rendering some individuals more or less susceptible to CD30+ LPDs, including primary cutaneous LPDs.[45] This might explain LyP patients' increased risk of developing HL and ALCL. Because LyP patients have a significantly increased risk of both lymphoid and nonlymphoid malignancies, an as-yet-undefined genetic defect that is not limited to lymphoid cells is suspected.[22]

Clinical Features

LyP lesions appear as self-healing papules, which may develop a necrotic center (**Fig. 39-1A**).[5] Occasionally, larger eschar-type ulcerated lesions result from angioinvasive LyP (type E) (**Fig. 39-1B**).[46] Typically, lesions in different evolutionary stages are present at the same time.[7,12] Most lesions are asymptomatic, but patients rarely experience itching. LyP lesions often appear in clusters and recur in the same region of the body. Extremities, trunk, and particularly the buttocks are most commonly affected. Lesions occur infrequently on the face, palms, soles, and anogenital areas and only rarely on mucous membranes.[47,48] These clinical observations raise the possibility that cytokines or chemokines released from epidermal keratinocytes or Langerhans cells may contribute to the development of LyP.

Patients experience the development of new lesions while others are regressing, and lesions may persist for several months.[7,12] LyP lesions occur in crops, often with long lesion-free intervals. LyP lesions often reoccur in the original site. In some women, LyP lesions appear to be modulated by the menstrual cycle or develop during pregnancy.[49] LyP lesions occur in crops, often with long lesion-free intervals. In other patients, one or a few lesions grow progressively to form a primary C-ALCL (**Fig. 39-1D**). Large lesions often ulcerate centrally and show some degree of spontaneous regression, even after 2 to 3 months. In a few patients, continual eruptions of papulo-nodules histologically typical of LyP occur in a well-circumscribed area, equivalent to limited plaque MF (**Fig. 39-1C**), which is also referred to as *persistent agminated LyP*.[50] In borderline lesions, the distinction between C-ALCL and LyP cannot be established (**Fig. 39-1F**); however, in most patients, follow-up clarifies the lesion type.[4]

C-ALCL usually presents as solitary or grouped (localized) rapidly growing tumors reaching several centimeters in diameter or thick plaques (**Fig. 39-1E**); presentation with multifocal tumors is rare. Tumors tend to undergo ulceration. Spontaneous complete or partial regression was reported in the literature to occur in 10% to 42% of the cases, but in our experience complete regression of C-ALCL is a rare phenomenon.[51] Spontaneous regression is associated with a good prognosis.[9]

Regional lymphadenopathy can develop and likely represents the local spread of tumor cells (**Fig. 39-2**). The prognosis does not appear to be affected by regional lymphadenopathy.[7,52,53] Regional lymph node enlargement can also represent dermatopathic

lymphadenopathy. Staging procedures are generally not warranted for asymptomatic patients with uncomplicated LyP.

The development of systemic symptoms of fatigue, fever, weight loss, night sweats, or bone pain should raise the possibility of systemic lymphoma complicating LyP. In these individuals, more extensive staging with imaging of the chest and abdomen (i.e., PET-CT) should be done. Abdominal or intrathoracic lymphadenopathy should be regarded as highly suspicious for nodal lymphoma. Bone lesions have been observed in some LyP patients who developed systemic CD30-positive ALCL (**Fig. 39-3**).

Staging procedures are recommended for C-ALCL.[54] Bone marrow examination is not recommended owing to the low frequency of involvement.[55] A Sézary preparation or flow cytometry of the peripheral blood is not necessary in patients with uncomplicated primary cutaneous CD30+ LPDs. A chest radiograph is recommended to exclude asymptomatic mediastinal lymphadenopathy, which can be a presenting feature of nodal ALCL or HL. International consensus recommendations for management and treatment of primary cutaneous CD30-positive lymphoproliferative disorders have been reported in detail by the European Organization for Research and Treatment of Cancer, the International Society for Cutaneous Lymphomas, and the United States Cutaneous Lymphoma Consortium.[54]

Because of overlapping histologic features, CD30+ LPDs need to be differentiated from other cutaneous lymphomas, especially large cell transformation of MF, by a careful clinicopathologic correlation.[54,56] The development of persistent patches, plaques, or

scaly erythematous lesions; hair loss; or onychodystrophy is indicative the presence of MF complicating LyP (**Fig. 39-1C**).

Morphology

LyP lesions vary in appearance, depending on their stage of development at the time of biopsy (**Fig. 39-4**). Early lesions reveal mainly perivascular and superficial dermal accumulations of atypical lymphoid cells surrounded by variable numbers of inflammatory cells (**Figs. 39-4A and Fig. 39-4C**). Neutrophils within the lumens of blood vessels are a nearly constant feature of LyP (**Fig. 39-4B**). Neutrophils may percolate through the epidermis, accounting for the pustular appearance of LyP lesions. Histiocyte/macrophages may be numerous. Plasma cells generally are not prominent. Fully developed or late lesions are often wedge-shaped, sometimes extending into the deep dermis with little or no involvement of the subcutis in most cases (**Fig. 39-4D**). Hair follicles and sweat glands may be infiltrated by atypical cells. Other unusual histopathologic patterns associated with LyP include follicular mucinosis[57]; syringotropic infiltrates and syringosquamous metaplasia[58]; angiocentric/angiodestructive (**Fig. 39-5G**)[46,59]; and a bandlike rather than wedge-shaped distribution of lymphoid cells.[60] The atypical cells often concentrate around and can be found within the lumina of blood vessels.

LyP comprises six main histologic or genetic types, with some overlapping features (**Table 39-2**; Figs. **39-4** and **39-5**).[6,7,46,61-63] Type A may resemble HL because of the presence of large Reed-Sternberg (RS)–like cells with prominent, often eosinophilic nucleoli (**Fig. 39-5A**). In some lesions, the atypical cells resemble

immunoblasts with amphophilic to basophilic cytoplasm, slightly eccentric nuclei, and conspicuous but usually not huge nucleoli. Surrounding the large atypical cells are variable numbers of neutrophils, eosinophils, histiocytes, and small lymphocytes (**Fig. 39-5B**). In some cases LyP type A cells have a plasmacytoid appearance (**Fig. 39-5C**). When large atypical cells are confluent or occur in sheets confined to the dermis, with relatively few inflammatory cells, the lesion is classified as LyP type C (**Fig. 39-5D**). Type B lesions resemble MF with epidermotropism of small-to-medium-sized atypical lymphocytes (see **Fig. 39-5E**). The predominant cell is a mononuclear cell with nuclear irregularities, sometimes cerebriform, without prominent nucleoli. Mitoses are infrequent. Epidermotropism is often present. Neutrophils and other inflammatory cells are not abundant. There is some controversy over whether LyP type B lesions represent a papular variant of MF.[64] In contrast to LyP lesions, the papular lesions in MF do not show spontaneous regression. It is not uncommon to find LyP lesions that contain a spectrum of cerebriform cells to larger immunoblasts or RS-like cells with abundant inflammatory cells that makes distinction from inflammatory skin disorders such as arthropod bite reactions, infestation, or drug eruptions challenging in those cases. These lesions can be referred to as type A/B to indicate a hybrid or mixed histology.[6,65-67] Different histologic LyP types can be observed in lesions of the same patient at the same time point.[60]

LyP type D shows a prominent epidermotropism of CD8-positive small-to-medium-sized atypical lymphocytes in a pagetoid pattern (**Fig. 39-5F**). It must be distinguished from cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma.[62] LyP type E

is characterized by angioinvasive infiltrates of mostly medium-sized CD30-positive and often CD8-positive atypical lymphocytes resulting in extensive necrosis and clinically in eschar-like ulcers (**Fig. 39-1B and Fig. 39-5G**).[46]

LyP with 6p25.3 rearrangement is distinctive for a biphasic pattern with an epidermotropic and a dermal nodular component (**Fig. 39-5H**). Intraepidermal cells are small-to-medium-sized, whereas dermal cells are larger, but only infrequently anaplastic. Dermal cells may infiltrate skin adnexae.[63]

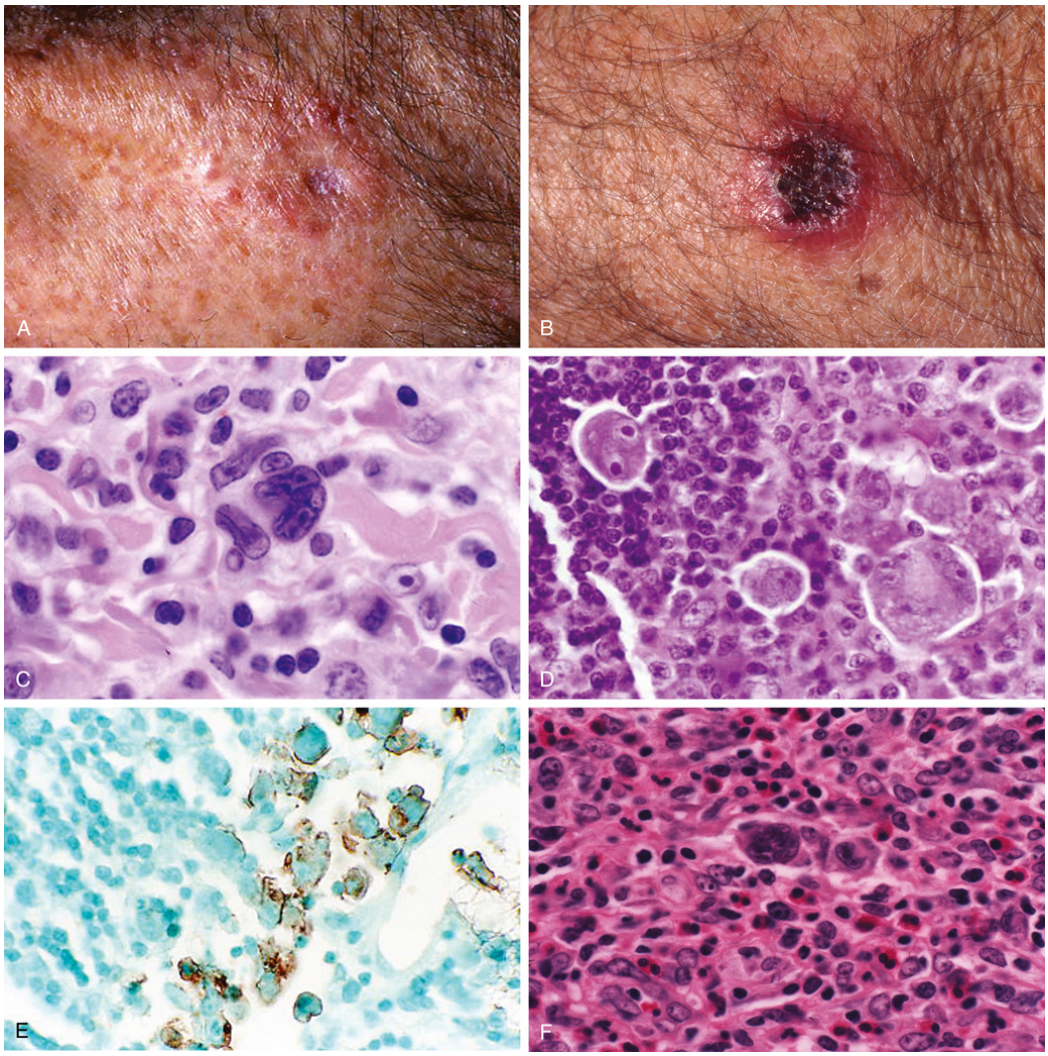

FIGURE 39-2 Patient with lymphomatoid papulosis, cutaneous anaplastic large cell lymphoma, and nodal lymphoma.**A,** Cluster of lymphomatoid papulosis (LyP) lesions. **B,** Ulcerated cutaneous anaplastic large cell lymphoma (C-ALCL). **C,** LyP showed anaplastic large cells in skin admixed with small lymphocytes and histiocytes. **D,** Lymph node with Reed-Sternberg (RS) cells and variants possibly representing classic Hodgkin lymphoma

(HL) versus an ALCL. **E,** Staining of tumor cells for CD15. **F,** In a different patient with LyP, multinucleated cells are surrounded by eosinophils in a lymph node. Such cases raise the differential diagnosis of HL versus ALCL.

C-ALCL commonly occurs as an extensive nodular dermal infiltrate, usually sparing the epidermis, and is composed almost entirely of large markedly pleomorphic anaplastic cells (**Fig. 39-6A–D**). The deep part of the lesion usually extends into the subcutis (**Fig. 39-6B**). Inflammatory cells are less frequent than in LyP; they are often nearly absent or confined to the lesion's periphery. An exception is the neutrophil-rich variant of C-ALCL (**Fig. 39-6E**), in which a confluence of neutrophils may obscure the appearance of the large atypical cells.[68,69]

Mitoses are common among the large atypical cells in LyP and especially in C-ALCL (**Fig. 39-5B and Fig. 39-6D**). Several studies indicate a high ratio of apoptotic cells to dividing cells in LyP. A significantly higher apoptotic index is found in LyP (12.5%) than in CD30-positive large T-cell lymphoma (3.1%).[70] The high rate of apoptosis in LyP can be attributed in part to the low expression of BCL2[71,72] and the high expression of the proapoptotic protein BAX.[73] The proportion of CD30-positive cells expressing death receptor apoptosis pathway mediators FADD and cleaved caspase 3 is significantly higher in primary cutaneous CD30-positive LPDs than in systemic ALCL.[74] In regressing LyP lesions, binding of CD30 and its ligand was detected by immunohistochemistry.[75] The tumor microenvironment in LyP and C-ALCL is characterized by the presence of numerous tumor-associated macrophages.[76]

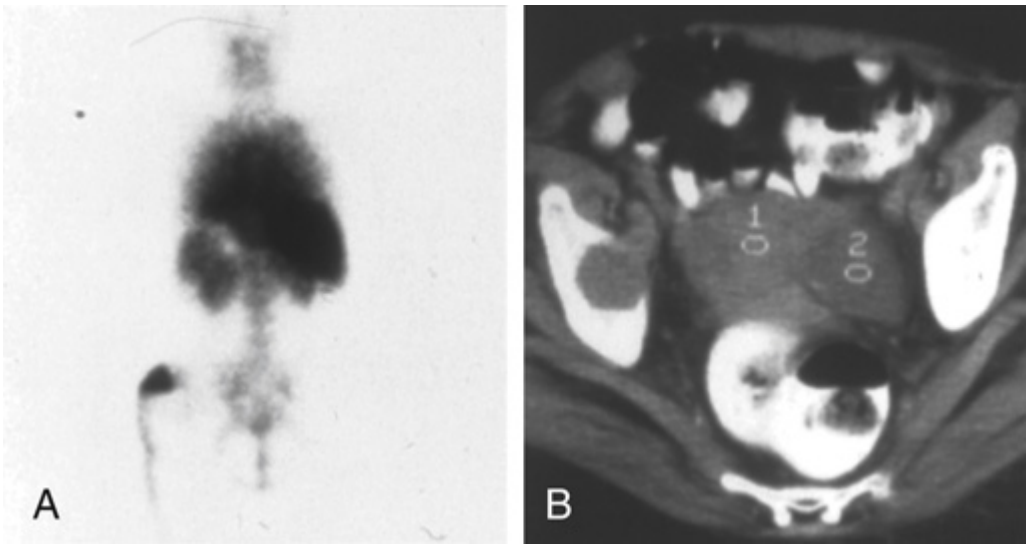

FIGURE 39-3 Bone lesions in two patients with cutaneous anaplastic large cell lymphoma secondary to lymphomatoid papulosis.**A,** Bone scan shows an area of increased activity in the right ileum. **B,** Computed tomography scan shows a large, round lytic lesion in the ileum of a second patient.

Borderline lesions contain an extensive infiltrate or sheets of atypical cells with focal extension into the subcutis, making them difficult to distinguish from LyP type C or C-ALCL.[54,77]

Immunophenotype

The usual immunophenotype of the large atypical cells in LyP (**Fig. 39-7A**) is that of activated helper T lymphocytes expressing CD4 and lymphocyte activation antigens such as CD30 (**Fig. 39-7B**), CD25, CD71, and HLA-DR.[36-38] Other T-cell antigens (e.g., CD3, CD2, CD5, CD7) are often not expressed, resulting in an aberrant T-cell phenotype (**Fig. 39-7C**).[78] A natural killer (NK)–cell phenotype for

the large atypical cells was noted in 10% to nearly 50% of cases in one study, but in none of 18 cases in another study.[60,79] In one series, one-third of cases had a CD8-positive phenotype.[60] CD8-positive LyP type D can be confused with aggressive epidermotropic CD8-positive cytotoxic T-cell lymphoma.[62,80] LyP type E, which expresses CD8 in 70% of cases, can mimic angioinvasive lymphomas such as extranodal NK/T-cell lymphoma, nasal type and peripheral T-cell lymphoma, not otherwise specified (NOS).[46] LyP with 6p25.3 rearrangement often displays a CD4/CD8 double-negative phenotype.

In most cases, the atypical cells express cytotoxic proteins, including TIA-1, granzyme B, and perforin (**Fig. 39-7D**).[81] ALK is negative, leukocyte common antigen (LCA; CD45) is characteristically expressed, and CD15 is absent in most LyP cases. EBV (EBER, LMP-1) is not found in LyP and C-ALCL. This profile helps distinguish LyP and ALCL from HL.[82]

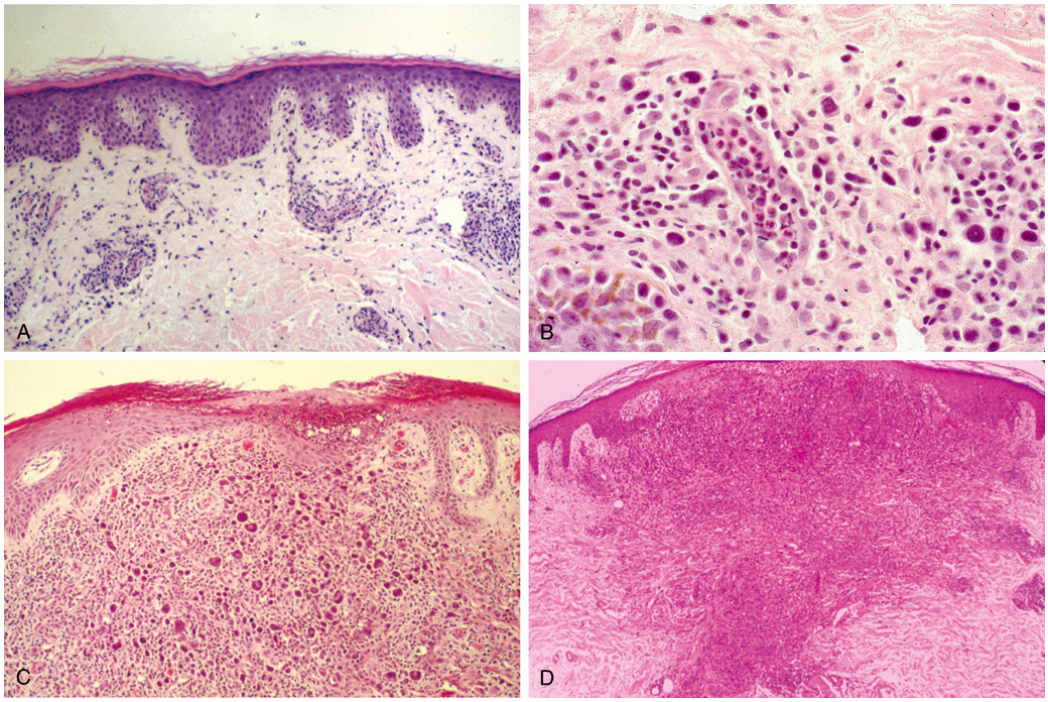

FIGURE 39-4 Histology of lymphomatoid papulosis.**A,** Early lesion with a perivascular accumulation of atypical lymphocytes. **B,** Collection of neutrophils in a dermal venule surrounded by anaplastic cells, characteristic of lymphomatoid papulosis (LyP). **C,** Erosion of the epidermis and scattered anaplastic cells in LyP. **D,** Fully developed wedge-shaped lesion.

C-ALCL also displays an activated T-cell phenotype and expresses CLA, may show loss of T-cell antigens, especially CD3, and frequent expression of cytotoxic molecules.[7,81,83] C-ALCL can exhibit a CD4-positive CD8-negative or CD4-negative CD8-positive phenotype, but double-positive or double-negative cases were also observed.[84] CD30 must be expressed by at least 75% of large cells.[85] Epithelial membrane antigen (EMA) and ALK staining is usually absent in C-ALCL, in contrast to systemic ALCL.[86,87] Rare cases of ALK-positive

C-ALCL, however, have been documented (**Fig. 39-8**) (see also Genetics and Molecular Findings).[88] IRF4/MUM1 encoded by the *IRF4* gene is strongly positive, and CD15 is expressed in about half of the cases.[89] C-ALCLs commonly express skin-homing molecules such as CCR4, CCR10, and CCR8 as well as homeobox gene *HOXC5* and CD158k.[90-94] SATB1 (special AT-rich sequence-binding protein) is a thymocyte nuclear protein and chromatin organizer that is crucial to T lymphocyte development. It is expressed in most LyP cases with T helper 17 cytokines and repressed T helper genes and is expressed in 40% of C-ALCL.[95]

Genetics and Molecular Findings

Clonal rearrangements of the T-cell receptor (TCR) beta or gamma chain genes have been detected in nearly all C-ALCLs and in most individual lesions of LyP.[21,65,96-100] The frequency of clonal rearrangements in LyP varies from 20% to 100%, depending on the method and the tissue (fresh versus archival tissue, with or without microdissection) used. Weiss and associates reported clonal or

oligoclonal T-cell populations detected by Southern blot in LyP.[98] In one patient studied at multiple sites, different clonal populations were detected. Using Southern blot, Whittaker and coworkers reported clones in most type B and mixed type A/B lesions but in no pure type A lesions of LyP.[100] Analyzing archival (i.e., formalin-fixed paraffin embedded) LyP biopsies, Greisser et al. found clonal T-cells in 20% to 70% of LyP lesions.[101] These results demonstrate that the lack of detection of T-cell clonality does not argue against the diagnosis of LyP. Using a more sensitive polymerase chain reaction (PCR) approach with variable region–specific primers, Chott and colleagues found dominant T-cell clones in 9 of 11 LyP patients.[65] In several patients, the same clone was detected in LyP lesions of different histologic types. A single-cell analysis of CD30-positive cells in LyP demonstrated that they were monoclonal in each of the 11 patients evaluated.[102] One patient who had progressed from LyP to C-ALCL had the same dominant clone detected in all lesions. Humme and coworkers performed molecular genetic analysis of skin lesions and blood of LyP patients by combining TCR-PCR and beta-variable complementarity-determining region 3 (CDR3) spectratyping.[103] They were able to detect a clonal T-cell population in 36 of 43 skin samples (84%) and in 35 of 83 blood samples (42%). Comparison of skin and blood demonstrated different T-cell clones, suggesting the unrelated nature of the clonal T cells in the skin and blood. Moreover, CDR3 spectratyping revealed a restricted T-cell repertoire in the blood, suggesting T-cell stimulation by an unknown antigen. The T-cell clone found in T-cell lymphomas that develop in patients with LyP is often the dominant clone in the LyP lesions.[21,65,96,104-107] Progression of LyP to C-ALCL appears to be

associated with an altered response to CD30 signaling. Although CD30 ligand expression is quantitatively increased in regressing CD30-positive skin lesions, CD30 ligation in C-ALCL cell lines that have progressed from LyP causes increased cell proliferation, associated with activation of NF κB.[42,75] CD30 ligation of NPM-ALK cell lines (e.g., Karpas 299) causes growth arrest by upregulation of cell cycle inhibitor p21 and accumulation of Rb (retinoblastoma) protein in the unphosphorylated state.[42,43] Thus, CD30 signaling plays an important role in the biology of LyP and ALCL.

Aberrant expression of T-cell antigens is common on large atypical cells in LyP. **D,** Staining for granzyme B in large atypical cells of LyP.

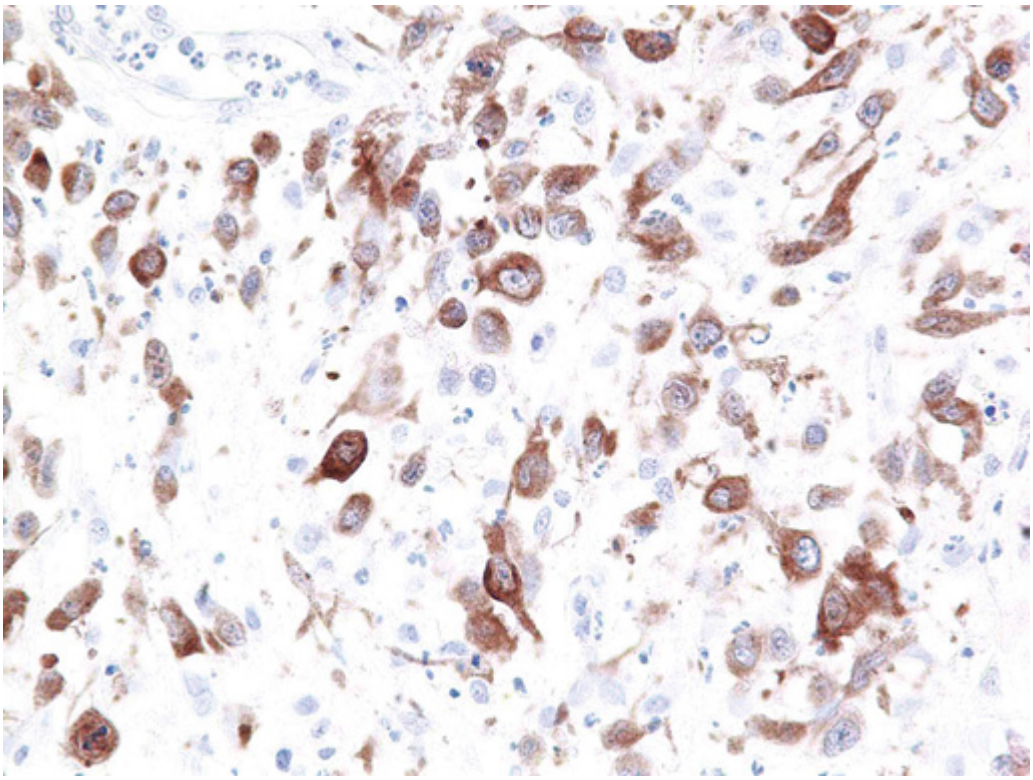

FIGURE 39-8 Cytoplasmic variant of anaplastic lymphoma kinase (ALK) in cutaneous anaplastic large cell lymphoma. Note the absence of staining over the nuclei of tumor cells. ALK was confirmed to be activated (phosphorylated) in this case.

DNA cytophotometry has shown that LyP cells may be diploid, hypertetraploid, or aneuploid. Willemze and associates found that aneuploidy is associated with a type A histology.[16,108,109] Cytogenetic studies of regressing lesions in LyP have demonstrated either a normal karyotype or numerical and structural abnormalities of chromosomes 7, 10, and 12.[110]

In contrast to systemic ALCL, the t(2;5)(p23;q35) translocations involving the ALK gene are absent in almost all C-ALCL cases.[110,111]

Nevertheless, rare cases of ALK-positive C-ALCL have been reported in children and adults, in some patients after insect bites.[112] Both, cases with nuclear and cytoplasmic staining typical of the t(2;5) chromosomal translocation and cases expressing cytoplasmic ALK protein indicating a variant translocation were found.[88,113-115] Most ALK-positive C-ALCL have an excellent prognosis. In ALK-positive cases, however, staging and close follow-up are essential because the skin lesions could represent the first manifestation of a systemic ALCL.[116,117]

C-ALCLs display multiple complex karyotypic abnormalities.[118] Multiple chromosomal imbalances including gains of 7q31 and losses at 6q16-21 and 13q34 were identified in almost half of C-ALCL cases.[94,119,120] The most common regions of oncogene amplification involved *CTSB* (8p22), *RAF1* (3p25), *REL* (2p12p12), and *JUNB* (19p13.2). Immunohistochemical studies support the amplification of *JUNB* in C-ALCL and LyP.[119,121] Allelic deletion at 9p21-22, causing inactivation of the *p16* tumor suppressor gene, has been reported in some C-ALCL.[122] Loss of 9p21.3 harboring the tumor suppressor gene CDKN2A is rarely found in C-ALCL, which contrasts with MF (tumor stage) and peripheral T-cell lymphoma, unspecified/NOS.[123]

IRF4 translocations with *DUSP22* rearrangement are found in approximately one-third of all cases.[124] In LyP, *IRF4* translocations are present in less than 5% of the cases.[124] The clinical outcome of *DUSP22*-rearranged C-ALCL and LyP does not differ from that of nonrearranged cases.

Gene rearrangements of *TP63* on chromosome 3q28 have been described in C-ALCL and exhibit an aggressive clinical course with

unfavorable outcome.[92] Expression of TP63 protein assessed by immunohistochemistry does not necessarily indicate an underlying *TP63* translocation which has to be evaluated by FISH analysis.

A novel recurrent *NPM*::*TYK2* gene fusion, resulting in constitutive STAT signaling, has been identified in LyP and C-ALCL.[125] RNA sequencing of C-ALCL revealed overexpression of genes involved in the neurotrophin signaling pathway (NTRK1, NTRK2, NTF3, NGF), which activates the JAK/STAT, PI3K/Akt and MEK/ERK signaling cascades that promote proliferation and survival.[126]

JAK-STAT signaling is a common feature of all ALCL subtypes and is found also in C-ALCL and LyP. Highly recurrent activating hotspot mutations and oncogenic fusion transcripts affecting the JAK and signal transducer and activator of transcription (STAT) signaling pathway (STAT5A and DNMT3A mutations) are reported as common molecular mechanisms of transformation occurring in up to 50% of CD30-positive LPDs.[127] Oncogenic fusions were found in the JAK/signal transducer and activator of transcription signaling pathway, namely *NPM*::*TYK2* in and *ILF3*::*JAK2* in two patients with LyP and clonally related MF.[128] These data suggest that somatic mutations in *JAK/STAT* genes play a key role in the pathogenesis of CD30-positive LPD.

Postulated Cell of Origin

The cell of origin for LyP and C-ALCL is an activated helper T lymphocyte expressing cytotoxic proteins.[36-38,78] Most cases express TCR alpha/beta, but a small subset of LyP is derived from gamma-delta T cells.[129] In vitro studies of the cytokine profile of the CD30-

positive cells point to a predominant Th2 type. The tumor cells secrete interleukin (IL)-4, IL-6, and IL-10 but not interferon (IFN)-gamma or IL-2. This is consistent with the usual functional profile of CD30-positive T lymphocytes.[130] The Th2 profile of LyP cells has justified the use of IFN-gamma in the treatment of primary cutaneous CD30-positive LPDs.[131] Alternatively, the CD30-positive cells in LyP and C-ALCL can have a phenotype (CD4 positive, $CD25^{high}$, CD45RO positive, surface transforming growth factor-beta [TGF-beta] positive) consistent with induced regulatory T cells that can suppress proliferation and cytokine production of CD25-negative T cells, at least in part by the action of the inhibitory cytokine TGF-beta.[132] The suppressor activity of natural regulatory T cells requires cell contact and is mediated by granzyme B, a property of CD30-positive cells in LyP.[81,133] In contrast to natural regulatory T cells, the CD30-positive cells in LyP and C-ALCL generally lack FOXP3 expression, which, however, is expressed by tumor infiltrating lymphocytes.[134] A subset of primary cutaneous CD30+ LPD associated with pseudoepitheliomatous hyperplasia was shown to be associated with Th17 cytokines IL-17 and IL-22 detected in the cytoplasm of CD30-positive cells.[135]

Clinical Course

LyP usually follows a chronic course, with intermittent lesion-free periods. In many patients, LyP persists for years and decades; occasionally it is a lifelong disease, but in some patients, particularly children, the disease may spontaneously remit.[136,137] There is often a long delay before the correct diagnosis of LyP is made. Most patients with LyP do not require active treatment, at least not initially. If

lesions are numerous, cause unsightly scarring, or occur on the face, hands, or other cosmetically undesirable areas, treatment with UVB narrow-band PUVA or low-dose oral methotrexate (starting at 10–25 mg/week) is most effective; 90% of patients treated with methotrexate achieve a significant reduction in lesions, but recurrence after withdrawal is commonly seen.[54,138] Long-term treatment (i.e., maintenance therapy with low-dose MTX) requires monitoring of side effects such as liver fibrosis. PUVA accelerates photoaging of the skin and increases the risk of skin cancer.[139] Bexarotene is an RXR (retinoid X receptor)-selective retinoid that decreases the number or duration of LyP lesions when given orally or applied as a gel.[140] High-potency steroids applied topically have minimal benefit. These treatments suppress LyP, but the lesions are likely to recur when treatment is stopped. X-irradiation is an effective treatment for nonregressing skin lesions complicating LyP.[7,54] An observation period of 2 to 3 months is usually recommended before irradiation, because some lesions regress spontaneously even after months. Multiagent chemotherapy is not recommended for LyP as recurrence is almost always seen. Importantly, treatment is unlikely to prevent the development of LyP-associated lymphomas, particularly MF or HL, but it may inhibit the progression to C-ALCL.[7] No definite risk factors for tumor progression have been identified. However, mutations of receptors for the lymphocyte growth inhibitory cytokine TGF-beta, high expression of *BCL2* genes, and expression of the cytoskeletal protein fascin have been associated with progression of LyP to C-ALCL.[29,71,141-143]

C-ALCL has a favorable prognosis with a 10-year-survival rate of 90%.[7,10] Multifocal presentation and involvement of loco-regional lymph nodes is not associated with impaired prognosis, but cases with extensive involvement of the legs and extracutaneous spread have a worse prognosis.[7,8,10,144] Sites of relapse in C-ALCL are unpredictable and may be either local or distant in the skin. Regional lymph nodes in proximity to large skin lesions are most often involved. Extracutaneous spread is often to the bony skeleton (see **Fig. 39-3**).[105] Patients with C-ALCL or HL may relapse with LyP after primary systemic therapy.[21,27,54,66] For solitary and localized C-ALCL lesions, surgical excision or radiation are the first-line treatment. Treatment for multifocal C-ALCL includes MTX and targeted therapy with brentuximab vedotin (BV), an anti-CD30-antibody conjugated to the cytotoxic agent monomethyl auristatin E (MMA).[54,145] Treatment with BV has been shown to be effective in cutaneous CD30+ LPD and in other CTCL with variable expression of CD30.[146,147] It represents a therapeutic alternative for patients with multifocal ALCL, extracutaneous spread, and LyP with disseminated lesions not responsive to other therapies. Treatment with BV is complicated by a sensory neuropathy affecting 40% of patients. Multiagent chemotherapy with CHOP (cyclophosphamide, hydroxydaunorubicin, Oncovin [vincristine], and prednisone or prednisolone) is only indicated for cases with extracutaneous spread and lack of response to BV.[7,9,54] Such aggressive approaches are not curative and should therefore be avoided because they produce unwarranted toxicity and limit future treatment options, particularly if the patient develops an extracutaneous lymphoma.

Table 39-3

ALCL, Anaplastic large cell lymphoma; *EBV,* Epstein-Barr virus; *HRS,* Hodgkin and Reed-Sternberg; *LCA,* leukocyte common antigen; *RS,* Reed-Sternberg; *TCR,* T-cell receptor.

* Refers to ALK-positive and ALK-negative ALCL with *ALK* rearrangement always present in the ALK-positive cases.

It is important to note that there is a tendency to treat LyP and C-ALCL too aggressively because of the high-grade histopathology, with many large atypical cells and high mitotic rate; frequent recurrences; and frequent clinicians' lack of familiarity with the natural history of the disease.[54,66] Clinicians may resort to systemic and even high-dose ablative chemotherapy with peripheral stem cell rescue or bone marrow transplantation.

Differential Diagnosis

Several neoplastic and non-neoplastic lesions may mimic primary cutaneous CD30+ LPDs either clinically or histologically (**Table 39-3**).

Systemic Anaplastic Large Cell Lymphoma

Systemic ALCL is associated with extranodal disease in 40% of cases, and the skin is the most common extranodal site.[148,149] Secondary skin lesions of systemic ALCL and C-ALCL can be histologically similar or even identical. Clinical features that favor primary C-ALCL are spontaneous regression, localized skin lesions, absence of lymphadenopathy, and age older than 30 years. Pathologic and immunophenotypic features that favor primary C-ALCL are tumor

cells in the epidermis, absence of t(2;5) and lack of ALK staining, absence or only partial expression of EMA, and expression of cutaneous lymphocyte antigen.[80,88,150] The distinction between systemic ALCL and C-ALCL, however, has to be based on radiologic staging examination (i.e., PET-CT).

Mycosis Fungoides

MF can occur before, after, or simultaneously with LyP.[65,96,104,151] MF lesions are usually erythematous and scaly patches or plaques that can clinically be readily distinguished from LyP. In rare cases, however, MF can present with small papular lesions (referred to as papular MF) that clinically may closely resemble LyP.[107,152] In contrast to LyP, the papular lesions in MF do not show spontaneous regression.[64] MF lesions can be readily distinguished morphologically from LyP type A by the absence of RS-like cells and neutrophils. Epidermotropic infiltrates typically found in LyP type B are histologically indistinguishable from MF (patch stage). Pagetoid lesions of LyP type D can resemble MF but LyP type D is clinically characterized by papular lesions with spontaneous regression and histologically by predominant expression of CD8 and CD30.[62] Transformed or tumor-stage MF can present with cohesive sheets of large CD30-positive tumor cells that resemble LyP type C and C-ALCL. Clinicopathologic correlation is essential to distinguish MF from LyP.

Systemic Hodgkin Lymphoma

HL can involve the skin as a secondary site. This is usually a consequence of direct obstruction from regional lymph nodes and

occurs only in advanced disease, when the diagnosis of HL is obvious.[153-155] Cutaneous lesions of secondary HL most commonly occur on the trunk. HL occurs with increased frequency in LyP patients and can appear before or after the clinical manifestations of LyP.[21,27,153,154] LyP can persist or recur after successful chemotherapy of HL and has no known adverse prognostic significance; therefore, the distinction of LyP from cutaneous HL is clinically important.[153] Clinically, LyP lesions regress, whereas those of secondary HL do not. LyP can be distinguished from HL by the expression of LCA and T-cell antigens and the absence of CD15 and EBV-associated antigens.[36,82,156]

Primary Cutaneous Hodgkin Lymphoma

Primary cutaneous HL is exceedingly rare and usually presents as solitary or multiple deep dermal lesions producing tumors on the extremities or trunk.[156,157] The skin lesions contain classic RS cells that have a CD15-positive, LCA-negative phenotype and may be positive for EBV-associated antigens (e.g., LMP-1).[156] Lesions of primary cutaneous HL do not regress. Patients with primary cutaneous HL appear to have a significant risk of developing nodal HL.[156]

Pityriasis Lichenoides

Pityriasis lichenoides et varioliformis acuta (PLEVA) and chronica (PLC) can be indistinguishable from LyP clinically and histologically (**Fig. 39-9**).[158-160] PLEVA tends to occur in patients younger than 30 years, is often not recurrent, and is not generally associated with an increased risk of developing malignant lymphoma.[161] However, a

French study did report that 29% and 80% of children with LyP and MF, respectively, presented with PLC before onset of their disease.[162] Similar to LyP, clonality of T cells can be found in many PLEVA cases.[163] However, PLEVA usually lacks the large, atypical RS-like cells of LyP type A and has few neutrophils or eosinophils. PLEVA shows apoptotic keratinocytes and extravasation of erythrocytes. Neutrophils in blood vessels characteristic of LyP are lacking in PLEVA. The lichenoid lymphoid infiltrate in PLEVA usually lacks the frequent CD30-positive cells found in LyP and contains a predominance of CD8-positive cells, whereas CD4-positive cells predominate in LyP.[164] However, Kempf et al. reported exceptional cases of PLEVA with numerous CD30-positive cells mimicking LyP.[160] Parvovirus B19 DNA was identified in 4 of 10 cases investigated, suggesting a possible link of parvovirus B19 to this subset of PLEVA cases. Similar cases have been designated as atypical PLEVA.[165]

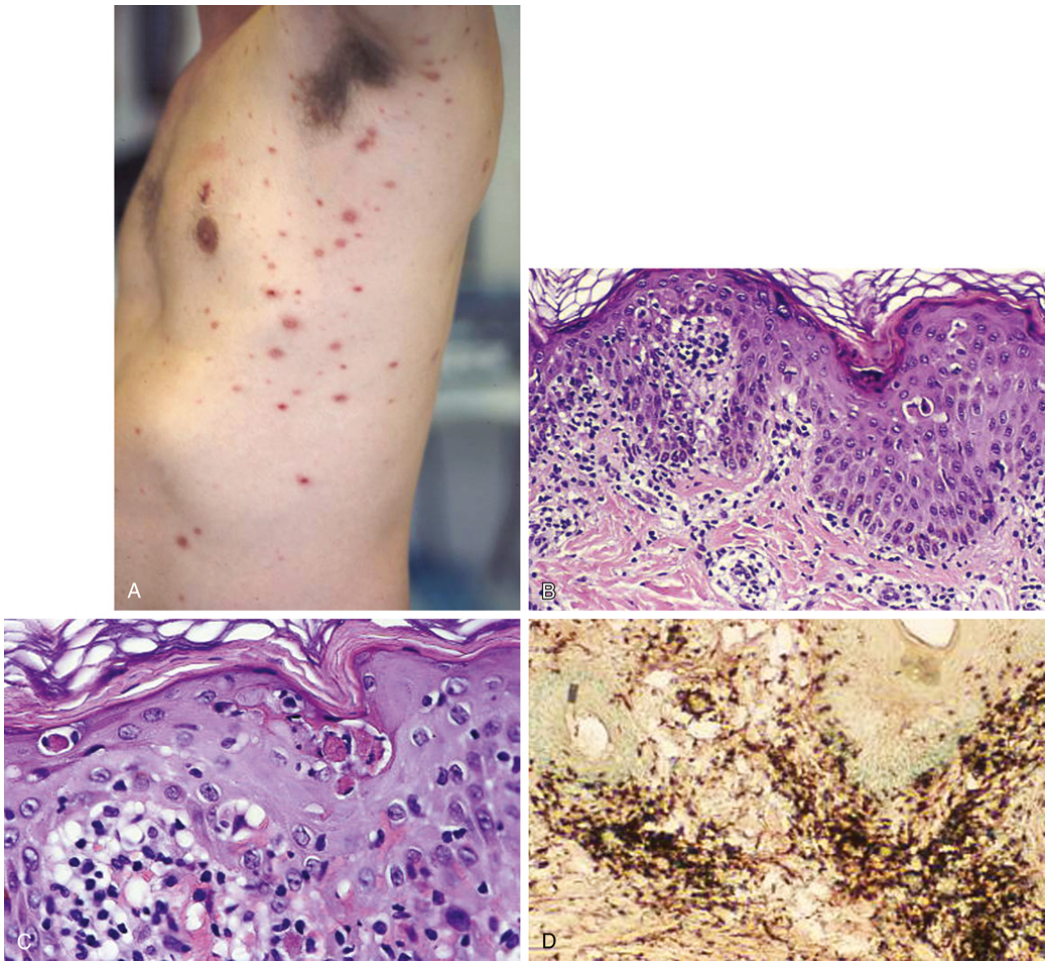

FIGURE 39-9 Pityriasis lichenoides et varioliformis acuta.**A,** Clinical photograph of centrally necrotic lesions on the thorax. **B,** Histology showing a lichenoid lymphoid infiltrate. **C,** Necrotic keratinocytes. **D,** Prevalence of CD8-positive cells.

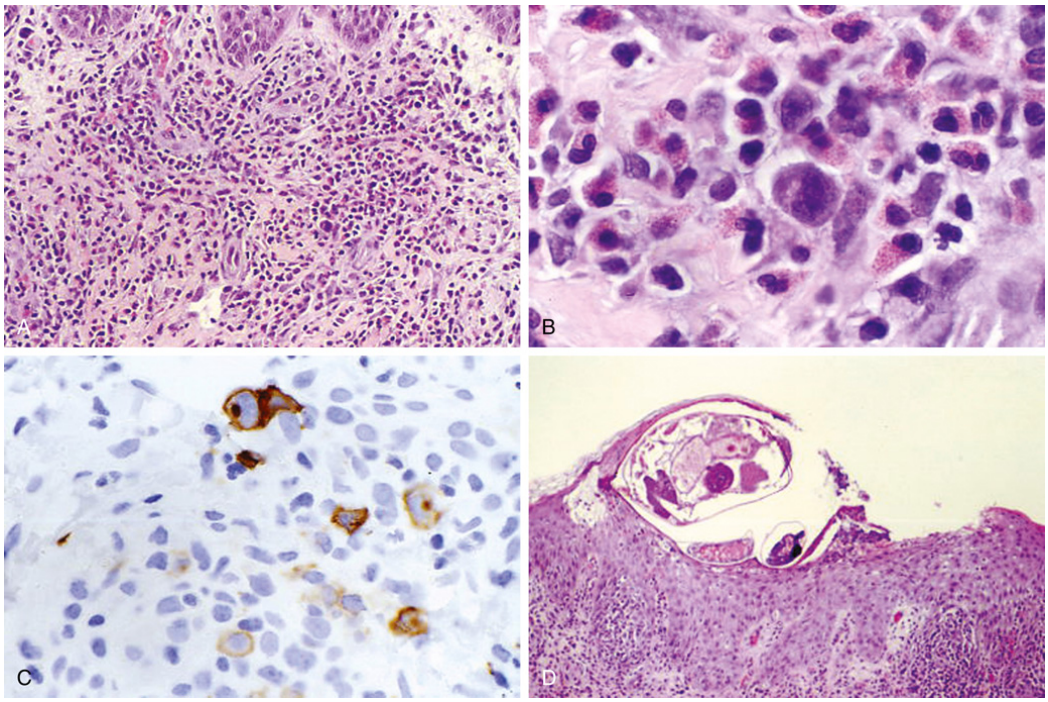

FIGURE 39-10 Nodular scabies resembling lymphomatoid papulosis.**A,** Dense dermal and perivascular infiltrate. **B,** Large atypical cell surrounded by eosinophils. **C,** CD30 stain of large atypical cells. **D,** Mite *(Sarcoptes scabiei var. hominis)* embedded in the epidermis.

Arthropod Bite and Infestation

LyP can be confused with arthropod bites clinically and histologically.[166] A clinical history and follow-up may be necessary to exclude arthropod bite from the differential diagnosis of LyP type A.

Nodular scabies can closely resemble LyP clinically and histologically as scabies lesions often contain CD30-positive immunoblasts surrounded by inflammatory cells, usually eosinophils.[167] The key distinction is demonstration of the offending

mite in scabies (**Fig. 39-10**). Detection of clonal T-cells is an argument for LyP and against inflammatory disorders such as arthropod bites and infestation.

Other Skin Conditions With CD30-Positive Large Cells

Several other cutaneous disorders that contain significant numbers of CD30-positive cells can enter into the differential diagnosis of primary cutaneous CD30+ LPDs. These include atopic dermatitis, molluscum contagiosum, herpes simplex infection, herpes varicella-zoster, tuberculosis, Milker's nodule, leishmaniasis, syphilis, lymphomatoid drug eruption, and hydroa vacciniforme lymphoproliferative disorder.[56,168-173] In most cases, the correct diagnosis can be established by clinical history, physical examination, and laboratory tests.

Pearls and Pitfalls

- Primary cutaneous CD30-positive T-cell lymphoproliferative disorder (CD30+ LPD) represents a spectrum including lymphomatoid papulosis (LyP), primary cutaneous anaplastic large cell lymphoma (C-ALCL), and borderline lesions with the expression of CD30 by atypical T-cells as the common denominator.
- LyP and C-ALCL display a phenotype of activated T helper cells, most commonly CD4 or CD8 positive, with frequent expression of cytotoxic markers and variable loss of T-cell

antigens, especially CD3. Most cases are T-cell receptor (TCR) alpha/beta positive, but rare gamma/delta positive cases have been documented.

- In contrast to many cases of systemic ALCL, C-ALCL does not express anaplastic lymphoma kinase (ALK), does not harbor a t(2;5), and shows only partial or focal expression of epithelial membrane antigen (EMA).
- Very rare cases of C-ALCL show positivity for ALK without evidence of systemic ALCL at the time of diagnosis. These cases appear to have the same biological behavior as ALK-negative C-ALCL.
- LyP and C-ALCL exhibit overlapping histologic and phenotypic features not only with each other, but also with other cutaneous T-cell lymphomas (CTCLs) such as mycosis fungoides (MF), but also with systemic ALCL or Hodgkin lymphoma (HL). Therefore, clinicopathological correlation is essential to differentiate LyP from other T-cell lymphomas, especially MF, and staging examination is crucial for the distinction from cutaneous involvement by systemic ALCL or HL.
- Certain inflammatory (e.g., pityriasis lichenoides [PL]) or infectious skin diseases (e.g., arthropod bite reaction, infestation, viral infections) may simulate LyP, especially the histologic type A. Except for PL, often harboring a T-cell clone, detection of clonal T-cells can serve as an additional diagnostic clue for LyP.
- LyP has chronic course characterized by recurrent papulo-nodular lesions undergoing spontaneous regression within

weeks to few months and an excellent prognosis. Approximately 15% to 20% of LyP patients develop MF, C-ALCL, systemic ALCL, or HL that may precede, occur synchronously, or occur after the diagnosis of LyP. Thus life-long follow-up is recommended.

- Treatment modalities for LyP include UV light (UVB narrow band or PUVA) or low-dose MTX, which is effective and indicated if numerous or socially stigmatizing lesions are present. Nodular lesions that may persist over months can be irradiated. In children, potent topical corticosteroids may be effective. Suppression of LyP during active treatment is usually temporary and does not prevent the development of LyP-associated lymphomas such as MF or HL. Thus a strategy without active intervention can be justified in individual patients.
- C-ALCL in general has a favorable prognosis with a 5-year survival rate of 90%. Loco-regional lymph node involvement in C-ALCL is not associated with impaired prognosis. There is an impaired prognosis (approximately 75%) in patients with extensive leg involvement or extracutaneous spread.
- Surgical excision or radiation are first-line therapies for solitary and localized C-ALCL. Low-dose MTX and CD30-targeting therapy with brentuximab vedotin are effective for multifocal C-ALCL.
- The correct diagnosis of LyP and C-ALCL is essential to avoid overtreatment. Neither LyP nor C-ALCL should be treated with multiagent chemotherapy with the exception of the rare

event of extracutaneous spread, if other treatment strategies such as CD30-targeting therapies are not effective.

Introduction

Cutaneous T-cell lymphomas (CTCLs) include, for the most part, mycosis fungoides (MF) and variants and cutaneous CD30-positive lymphoproliferative disorders, but other rare subtypes may be the source of diagnostic and therapeutic challenges. Some of these rare lymphomas show overlapping clinicopathologic features, and distinction from MF may be difficult or even impossible without proper history and complete clinical information. Despite extensive phenotypic and genotypic studies, a few cases may defy precise classification. In this context, some considerations are necessary.

Epidermotropism is not diagnostic of any type of cutaneous lymphoma. It can be encountered in different variants of CTCL and

rarely in cutaneous B-cell lymphomas as well. Prominent epidermotropism of single lymphocytes (pagetoid epidermotropism), on the other hand, is usually observed in some cases of MF (pagetoid reticulosis, cytotoxic variants of MF) and in cutaneous aggressive cytotoxic natural killer (NK)/T-cell lymphomas (primary cutaneous γδ T-cell lymphoma [pcγδTCL], cutaneous aggressive epidermotropic CD8-positive cytotoxic T-cell lymphoma, and cutaneous extranodal NK/T-cell lymphoma, nasal-type [cENKTCL-NT]).

Prominent involvement of the subcutaneous fat with "rimming" of adipocytes is not synonymous with subcutaneous panniculitis-like T-cell lymphoma (SPTCL). It can be encountered in other types of CTCL as well (particularly pcγδTCL and cENKTCL-NT). Although association with Epstein-Barr virus (EBV) is typical of cENKTCL-NT, other T-cell and B-cell neoplasms can be positive for EBV, which may raise challenges for accurate diagnosis.

Many of the rare forms of cutaneous T-cell lymphoma have a cytotoxic phenotype. The histopathologic findings and differential diagnosis of these lesions are summarized in **Table 40-1**.

Primary Cutaneous CD8-Positive Aggressive Epidermotropic Cytotoxic T-Cell Lymphoma

Definition

This is a cutaneous lymphoma composed of CD8-positive cytotoxic T lymphocytes, characterized morphologically by prominent epidermotropism and clinically by an aggressive clinical course.[1-4] In the past, this lymphoma was classified as either aggressive MF (MF

tumeur d'emblée) or generalized pagetoid reticulosis (Ketron-Goodman type).

Synonyms and Related Terms

The same term is used in all contemporary classification systems: the International Consensus Classification (ICC, 2022); the revised World Health Organization (WHO) 4th edition of the Classification of Tumours of Haematopoietic and Lymphoid Tissues (2017), and the proposed WHO 5th edition of the Classification of Tumours of Haematopoietic and Lymphoid Tissues (2022).

Epidemiology

The tumor occurs in adults of both sexes with a slight male predominance. Only one case has been reported in a child.[5]

Etiology

The etiology is not known.

Clinical Features

Patients have localized or, more frequently, generalized patches, plaques, and tumors, almost invariably ulcerated (**Fig. 40-1**). Involvement of mucosal regions is common. Before a case is classified as primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma, it is crucial to exclude a diagnosis of MF or of lymphomatoid papulosis.

Morphology

Histology reveals a plaquelike, nodular, or diffuse proliferation of lymphocytes with marked epidermotropism (**Fig. 40-2**). Although

prominent epidermotropism may confer a so-called “pagetoid” appearance to the infiltrate, it may be less pronounced or even missing in some lesions, particularly in advanced stages; thus, lack of epidermotropic lymphocytes is not sufficient to rule out this entity. Spongiosis and intraepidermal or subepidermal vesiculation may be observed. Invasion and destruction of adnexal skin structures are common, but angiocentricity and angiodestruction are infrequent. Cytomorphology is variable and can be characterized by small, medium-sized, or large pleomorphic cells.

Table 40-1

FIGURE 40-1 Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma.Partly ulcerated papules, plaques, and tumors.

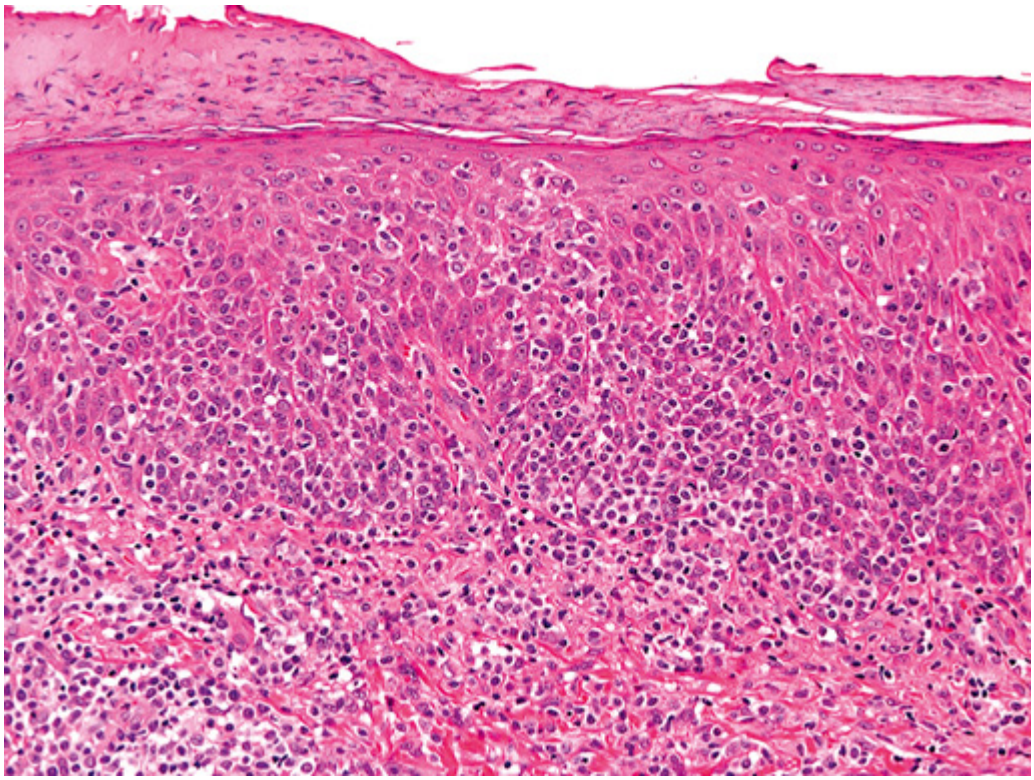

FIGURE 40-2 Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma.Prominent (pagetoid) epidermotropism of neoplastic lymphocytes.

Immunophenotype

Immunohistology reveals a characteristic phenotypic profile of neoplastic lymphocytes ($\beta F1^+$, $TCR\gamma^-$, $CD2^{-/+}$, $CD3^+$, $CD4^-$, $CD5^{-/+}$, $CD7^+$, $CD8^+$, TIA-1^+, granzyme B^+, $CD30^-$, $CD45RA^+$, $CD45RO^-$, $CD56^-$; **Fig. 40-3**), but pan–T-cell markers may be lost. EBV is not detectable in neoplastic cells.

Genetics

T-cell receptor (TCR) genes are monoclonally rearranged. Array comparative genomic hybridization has shown that gains (particularly in chromosomes 3, 7, 8, 11, 17, 18, and 22) are more frequent than losses (found frequently at 1p, 9p21, suggesting a role of *CDKN2A,* 13q, and 16p).[6-8] One study suggests this lymphoma could be a result of overactivation of the JAK2 signaling pathway via structural changes in *JAK2* and *SH2B3*.[9]

Clinical Course

The prognosis is poor, with an estimated 5-year survival of less than 10%. The disease often disseminates to the lung, testis, and central nervous system.

Differential Diagnoses

Distinction from cases of CD8-positive MF and from lymphomatoid papulosis type D is made mainly based on the clinical presentation and behavior. In contrast to MF, patients with primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma present from the beginning with generalized plaques and tumors. Lymphomatoid papulosis type D is characterized by the typical "waxing and waning" of papules and small nodules.[10]

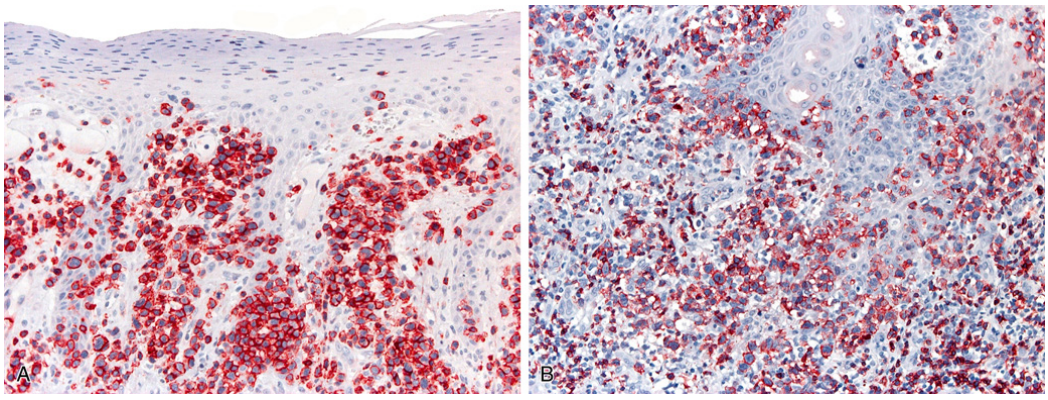

FIGURE 40-3 Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma. Strong positivity for CD8 **(A)** and βF1 **(B)**.

Pediatric patients with a clinical presentation associated with sun exposure and positivity for EBV should be classified as hydroa vacciniforme lymphoproliferative disorder (LPD), either classic or systemic (see **Chapter 29**). Cases of CD8-positive T-cell lymphoma with exclusive involvement of the subcutis with rimming of fat spaces should be classified as SPTCL. Distinction of primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma from cutaneous γδ T-cell lymphoma is achieved mainly by demonstration of expression of αβ and negativity for γδ. Primary cutaneous acral CD8-positive LPD is characterized by dermal infiltrates lacking epidermotropism and usually by solitary, nonulcerated lesions (mostly on the ears and face).

Primary Cutaneous γδ T-Cell Lymphoma

Definition

pcγδTCL is a tumor of cytotoxic γδ T lymphocytes with specific tropism for the skin.[1,2] This lymphoma shows overlapping features with other CTCLs, particularly MF, SPTCL, and primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma. Cases of pcγδTCL in the past have been classified as aggressive MF (MF tumeur d'emblée), generalized pagetoid reticulosis (Ketron-Goodman type), or subcutaneous T-cell lymphoma. It is crucial to remember that a γδ phenotype is not unique to pcγδTCL. It can be observed in several cutaneous (and extracutaneous) lymphoma types, including MF.[11,12]

Synonyms and Related Terms

The same term is used in all contemporary classification systems: ICC (2022), revised WHO 4th edition (2017), and proposed WHO 5th edition (2022).

Epidemiology

pcγδTCL occurs in adults, with an equal distribution between men and women. Cases in children have been reported.[13]

Etiology

Etiologic factors are not known.

Clinical Features

Patients have localized or generalized patches, plaques, and tumors, often ulcerated, and the clinical features may be indistinguishable from those of advanced MF (**Fig. 40-4**). In some patients, lesions are restricted to the lower extremities. Subcutaneous tumors may also be seen. Involvement of the mucosal regions is common. Lactate

dehydrogenase is elevated in most patients,[14] whereas bone marrow involvement is uncommon. A hemophagocytic syndrome is a frequent complication. Almost one-fourth of the patients had an associated autoimmune disorder in one study,[14] and onset of pcγδTCL has also been observed during treatment with etanercept for rheumatoid arthritis.[15]

In addition to cutaneous and hepatosplenic cases, γδ T-cell lymphomas can be observed at other nodal or extranodal sites,[16] thus underlying the need for staging investigations.

Morphology

Histology reveals a diffuse proliferation of lymphocytes (**Fig. 40-5**), usually with prominent involvement of the subcutaneous tissue (**Fig. 40-6A**). Epidermotropism is variable and may be marked (pagetoid epidermotropism; **Fig. 40-6B**). Although epidermotropic lesions may resemble those observed in MF, unlike in MF, intraepidermal vesiculation and prominent edema within the papillary dermis are not uncommon in pcγδTCL. Angiocentricity or angiodestruction is a frequent finding (**Fig. 40-7**), sometimes with necrosis of the overlying epidermis. Cytomorphology is variable (small, medium-sized, or large pleomorphic cells) and is not related to prognosis. The neoplastic cells show frequent apoptosis, and admixed macrophages contain prominent phagocytosis of nuclear debris (**Fig. 40-8**).

Immunophenotype

Immunohistochemical demonstration of expression of TCRγ or TCRδ is a prerequisite for the diagnosis (**Fig. 40-9**).[12] In fact, lack of αβ expression is not synonymous with γδ differentiation, as "TCR-

silent" (null-cell) cases negative for both αβ and γδ may be observed.[16] Immunohistology reveals a characteristic phenotypic profile of neoplastic lymphocytes ($TCR\gamma^+$, $TCR\delta^+$, $\beta F1^-$, $CD3^+$, $CD4^-$, $CD8^-$, TIA-1^+, $CD56^+$, $CD57^-$).[17] Some pan–T-cell markers may be lost, especially CD5. Almost one-fourth of pcγδTCL has expression of CD4 or CD8.[18] EBV is not present in the neoplastic cells. The classification of rare cases of CTCL with a γδ phenotype and positivity for EBV is ambiguous, as extranodal NK/T-cell lymphomas may exhibit a T-cell phenotype.[14,19,20] As mentioned, cutaneous aggressive cytotoxic lymphomas present several overlapping features, and classification of a given case may be subjective.

FIGURE 40-4 Primary cutaneous γδ T-cell lymphoma.Simultaneous occurrence of ulcerated tumor on the ear **(A)** and infiltrated patches and plaques on the leg **(B)**. These last lesions are indistinguishable from mycosis fungoides.

Genetics

Molecular biology shows a monoclonal rearrangement of the TCR genes. γδ T-cell lymphomas (both cutaneous and extracutaneous) have a different molecular profile from αβ T-cell lymphomas, with

overexpression of genes of NK-cell–associated molecules, such as killer-cell immunoglobulin-like receptor *(KIR)* genes *(KIR3DL1, KIR2DL2, KIR2DL4)* and killer-cell lectin-like receptor genes *(KLRC1, KLRC2, KLRC4)*.[21] Hepatosplenic γδ T-cell lymphoma shows a different molecular profile from γδ T-cell lymphomas arising at other sites, including the skin.[21] Cytogenetic abnormalities including amplifications and deletions, and breakpoints in different chromosomes (1q, 15q, 7 q, 9p, 14 q, and 18q) were found.[22,23] Multiple alterations affecting several oncogenic pathways, including STAT3, STS5B, MYC, JAK/STAT, and MAPK and chromatin mutations have been described.[22-24]

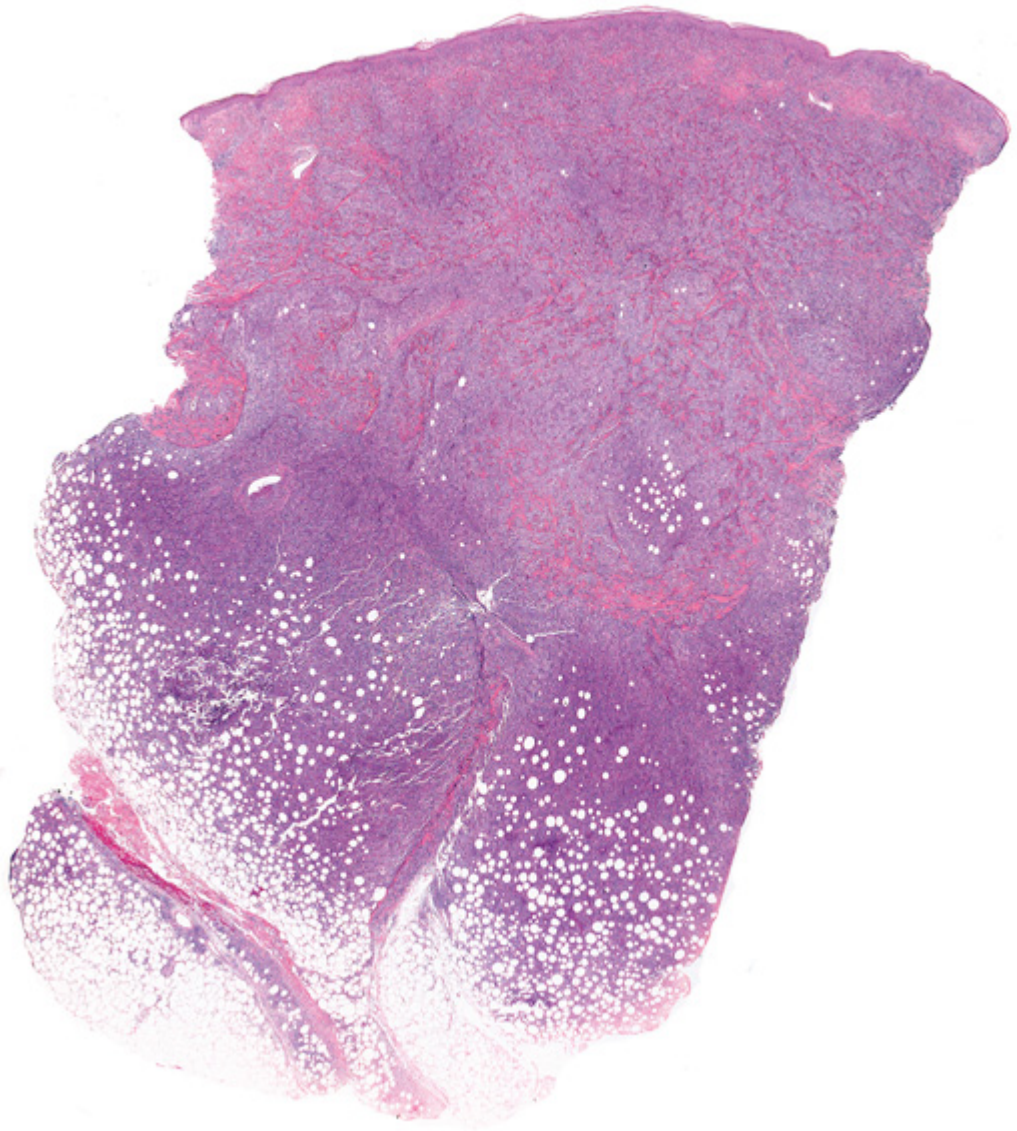

FIGURE 40-5 Primary cutaneous γδ T-cell lymphoma. Dense, diffuse infiltrates involving the entire dermis and subcutaneous tissue.

Clinical Course

The prognosis of patients with pcγδTCL is poor, although rare patients may show a prolonged course.[25] As MF can present with a γδ cytotoxic phenotype, at least some of the cases of pcγδTCL

reported to have an indolent behavior may in fact have been examples of MF. The prognostic significance of epidermal involvement by pcγδTCL is unclear.[24,26]

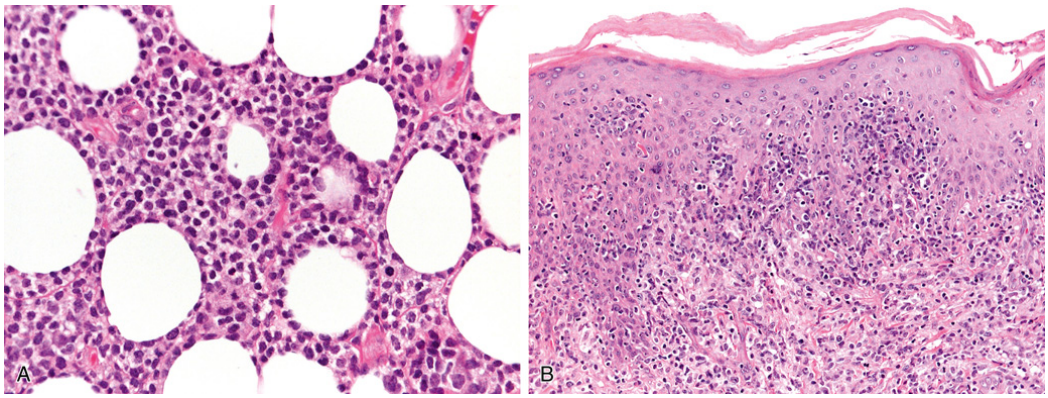

FIGURE 40-6 Primary cutaneous γδ T-cell lymphoma.A, Subcutaneous involvement mimicking the pattern of subcutaneous panniculitis-like T-cell lymphoma. **B,** Epidermotropism of pleomorphic lymphocytes.

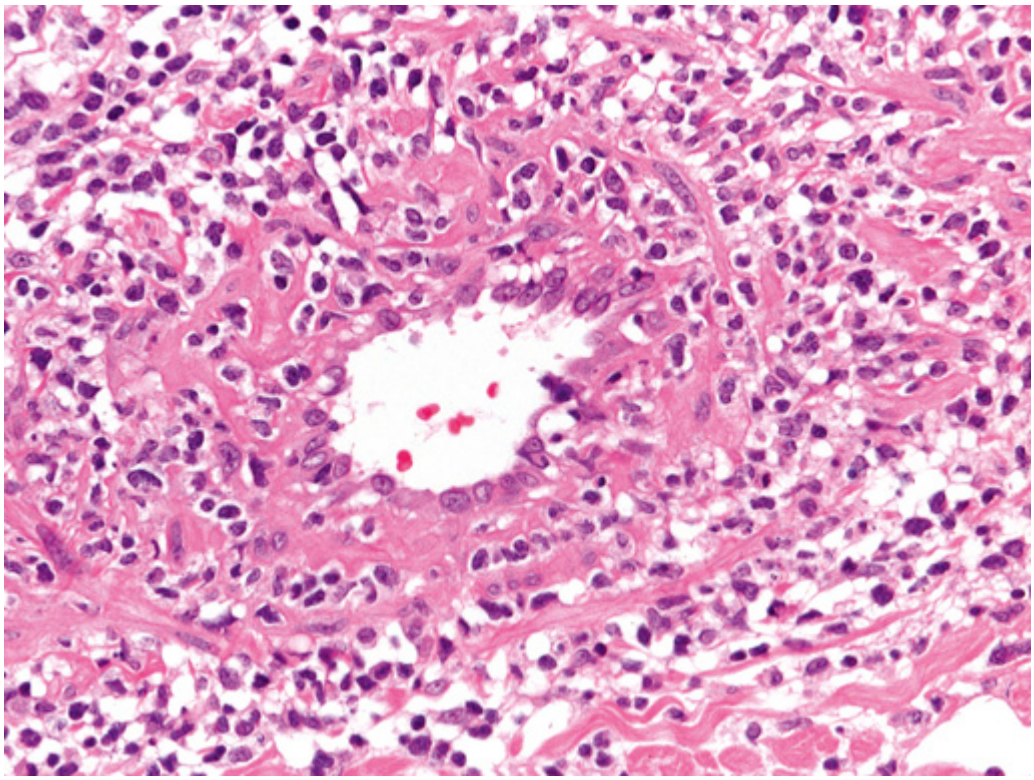

FIGURE 40-7 Primary cutaneous γδ T-cell lymphoma.Angiotropic lymphocytes with predominantly medium-sized pleomorphic nuclei.

Differential Diagnosis

Involvement of the dermis and epidermis allows a clear morphologic distinction from SPTCL, in which only the subcutaneous tissues are involved. Distinction from rare cases of conventional MF with γδ T-cell phenotype is made exclusively on the basis of the clinical presentation and behavior. In contrast to MF, patients with pcγδTCL show rapidly growing patches, plaques, and tumors already at onset of the disease. The distinction of pcγδTCL from primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma

is achieved by demonstration of the γδ phenotype of neoplastic cells. Distinction from cutaneous cENKTCL-NT may be impossible on morphology alone, as these two entities may show a similar, prominent involvement of both the epidermis and the subcutis. Demonstration of a γδ phenotype is suggestive of pcγδTCL, and positivity for EBV strongly supports a diagnosis of cENKTCL-NT. CD30 positivity and ALK negativity, along with the presence of hallmark cells, can mimic ALK-negative anaplastic large cell lymphoma. However, the presence of rimming of adipocytes and TCR γδ phenotype favors pcγδTCL.[27]

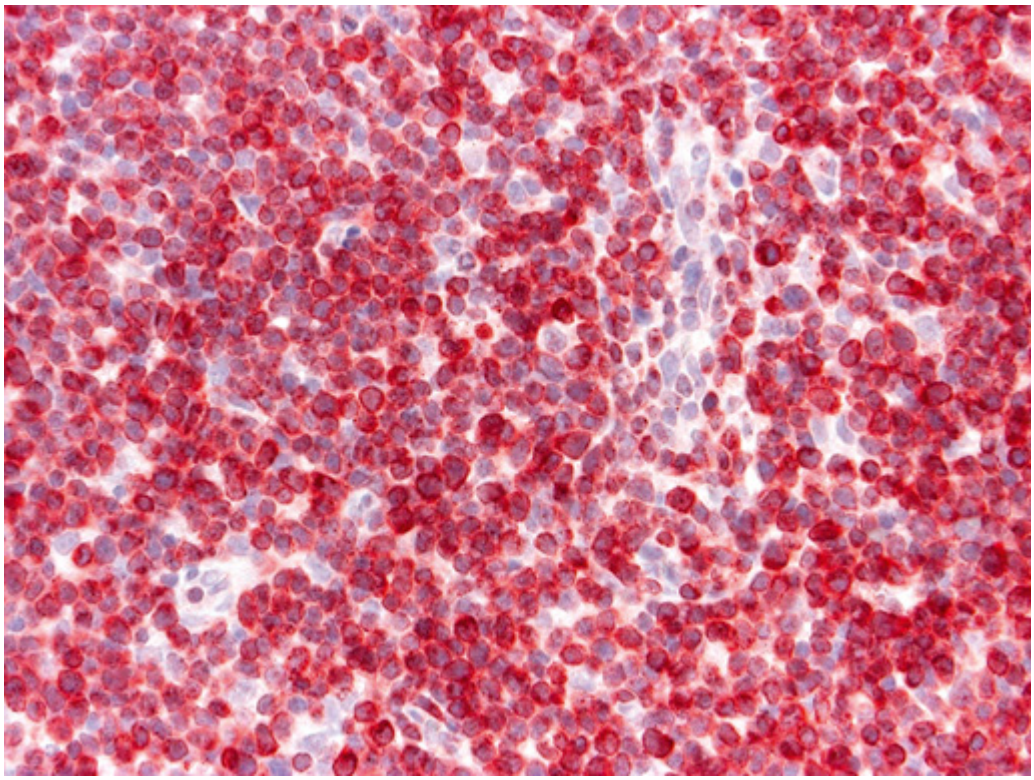

FIGURE 40-9 Primary cutaneous γδ T-cell lymphoma.Strong positivity for anti-TCRγ antibody.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Definition

SPTCL is an αβ CD8-positive cytotoxic T-cell lymphoma restricted to the subcutaneous fat, characterized by histopathologic features that mimic those of a lobular panniculitis.[1,28,29] The association with hemophagocytic syndrome (HPS) in older cases led to misdiagnosis as malignant histiocytosis, termed “histiocytic cytophagic panniculitis.” Cases with a γδ T-cell phenotype were formerly included with SPTCL, but based on aggressive behavior are now

classified as pcγδTCL. In this context, a positive staining for the αβ receptor is mandatory for the diagnosis of SPTCL. Diagnostic criteria for SPTCL have evolved over the years.

Synonyms and Related Terms

The same term is used in all contemporary classification systems: ICC (2022), revised WHO 4th edition (2017), and proposed WHO 5th edition (2022).

Epidemiology

Patients are adults of both sexes, often with a variably long history of panniculitis (particularly lupus erythematosus panniculitis [LEP]). Reports in children exist, with variation in the clinical behavior.[30,31]

Etiology

The etiology of SPTCL is unknown. Autoimmune disorders, particularly lupus erythematosus, have been reported in a proportion of patients.[32,33] In a patient with lupus, the diagnosis should be made with caution, as lupus profundus can resemble SPTCL. The disease has been observed also in patients receiving immune modulatory drugs[34] and in an immunosuppressed patient after cardiac transplantation.[35]

A study showed that neoplastic lymphocytes express CCL5, a ligand for the C-chemokine receptor 5 expressed by adipocytes, providing a possible explanation for the tropism of neoplastic T lymphocytes for the adipose tissues.[36]

Clinical Features

Patients present clinically with solitary or multiple, infiltrated, subcutaneous (panniculitis-like) plaques or tumors, mostly located on the extremities (**Fig. 40-10**). Partial or complete spontaneous resolution of individual lesions may be observed, and patients respond well to immunomodulatory therapy in most instances.[37] A history of autoimmune disorders, particularly lupus erythematosus, is present in about 20% to 40% of patients,[33,37] and they may show positivity for antinuclear antibodies and subsets, hematologic changes, renal changes, and positive result of immunofluorescence testing on lesional skin.[32] In a small minority of patients, there are accompanying symptoms such as fever, malaise, fatigue, and weight loss. A hemophagocytic syndrome may be seen in advanced stages or, rarely, at first presentation and can be the cause of death.[32] A hemophagocytic syndrome, however, is more common in pcγδTCL or in cENKTCL-NT.

FIGURE 40-10 Subcutaneous panniculitis-like T-cell lymphoma.Large, ill-defined, infiltrated subcutaneous plaque.

Morphology

Histopathology reveals dense, nodular, or diffuse infiltrates of atypical medium and (rarely) large pleomorphic lymphocytes confined to the subcutaneous fat with the histopathologic pattern of

a lobular panniculitis (**Fig. 40-11A**). Because of morphologic overlap with lobular panniculitis, identification of cytologic atypia is an important diagnostic criterion. Clusters of neoplastic T lymphocytes are almost never observed outside of the subcutaneous tissues, and epidermotropism is never found. Neoplastic cells within the subcutaneous fat are arranged in small clusters or as solitary units around the single adipocytes (so-called "rimming" of the adipocytes; **Fig. 40-11B**). Fat necrosis is often a prominent feature and is usually combined with a prominent histiocytic infiltrate, often with formation of granulomas. A specific diagnosis may be impossible in cases with prominent necrosis and secondary degenerative changes. Angiocentricity or angiodestruction is uncommon.

Although rimming of adipocytes is a typical histopathologic feature of SPTCL, a similar phenomenon can be observed in virtually all lymphomas with prominent involvement of the subcutaneous fat (both T-cell and B-cell lymphomas) and in reactive subcutaneous infiltrates.[38] SPTCL and LEP may be challenging differentials, with caution warranted in cases with ambiguous histologic features.[39]

Immunophenotype

SPTCL is characterized by an αβ T-suppressor phenotype ($\beta F1^+$, $TCR\gamma^-$, $CD3^+$, $CD4^-$, $CD8^+$, TIA-1^+, $CD30^-$, $CD56^-$; **Fig. 40-12A–C**). Particularly in recurrent lesions, βF1 expression may be partially lost by neoplastic cells, but it is usually retained by at least a proportion of them. A negative staining for TCRγ is helpful in these cases. Staining for proliferation markers highlights the pattern of

neoplastic cells arranged in small clusters and around the adipocytes (**Fig. 40-12D**).

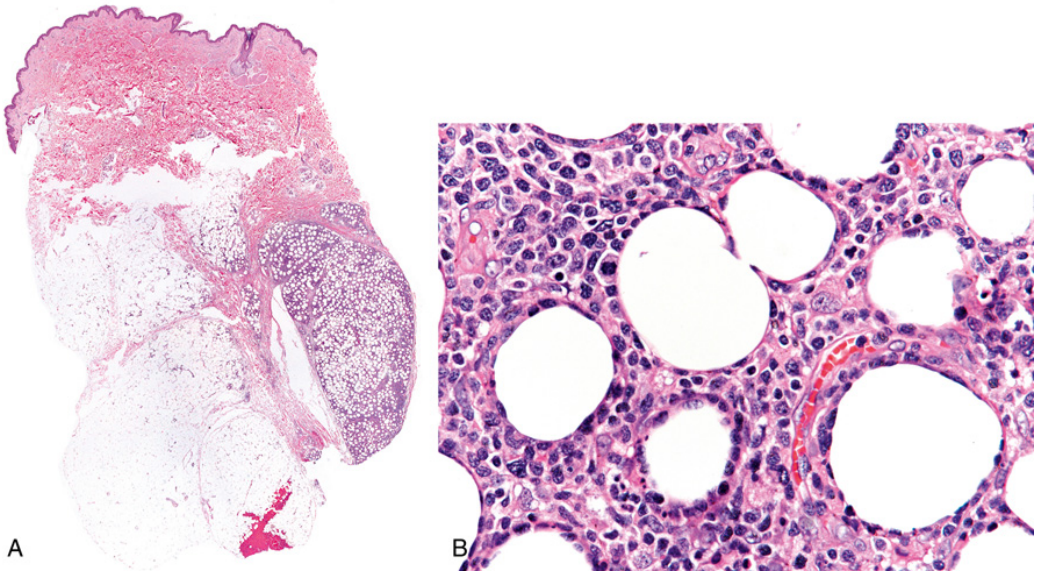

FIGURE 40-11 Subcutaneous panniculitis-like T-cell lymphoma.A, Exclusive involvement of the subcutaneous fat with the pattern of a lobular panniculitis. **B,** Pleomorphic lymphocytes showing rimming of adipocytes.

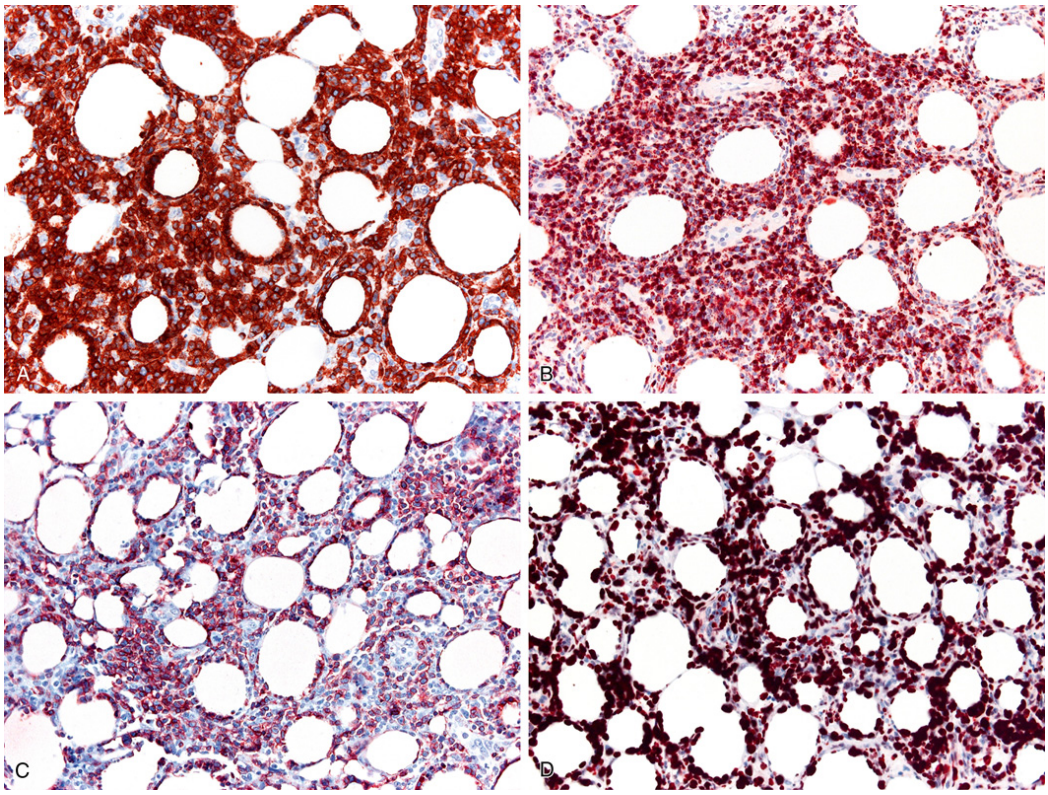

FIGURE 40-12 Subcutaneous panniculitis-like T-cell lymphoma. Immunohistology reveals positivity for CD8 **(A)**, granzyme B **(B)**, and βF1 **(C)**. Note high proliferation and positivity of lymphocytes around the adipocytes, as detected by Ki67 **(D)**.

Genetics

Molecular analysis of the TCR genes shows a monoclonal rearrangement in most cases. Genetic analyses are hindered by the small number of neoplastic cells, and only limited (and unconfirmed) data are available. Gains of chromosomes 2q and 4q and losses of chromosomes 1pter, 2pter, 10qter, 11qter, 12qter, 16, 19, 20, and 22 have been described in a study of nine patients.[40] In the same study,

allelic *NAV3* aberrations were found by loss of heterozygosity and fluorescence in situ hybridization analyses in almost half of the cases.[40] Studies have identified a germline mutation of *HAVCR2,* encoding T-cell immunoglobulin mucin 3 (TIM3) in patients with sporadic tumors.[41,42] This mutation is seen with higher frequency in Asian populations. Various triggers have been proposed for patients without germline mutations, including viral infection and autoimmunity.[43]

Clinical Course

SPTCL is an indolent lymphoma with good prognosis and a 5-year overall survival of more than 80%.[32] Immunosuppressive drugs should be considered as the first-line treatment instead of polychemotherapy.[33,37] The onset of HPS is a poor prognostic sign.[32] Such cases are significantly associated with *HAVCR2* mutations; therefore, genetic screening should be recommended in such cases. The presence of angiotropism was linked to a worse prognosis in one study.[44]

Differential Diagnoses

Differentiation of SPTCL from LEP (**Fig. 40-13**) may be impossible in some cases, and it has been proposed that the two diseases represent two ends of a spectrum of panniculitic T-cell dyscrasia.[45] The presence of clusters of CD123-positive plasmacytoid dendritic cells favors the diagnosis of LEP (**Fig. 40-13E**),[46] whereas the finding of pleomorphic, CD8-positive cytotoxic T lymphocytes with high proliferation favors SPTCL. Plasma cells are often present within the inflammatory infiltrate in LEP (**Fig. 40-13D**) but not in

SPTCL. Nodular aggregates of B cells, sometimes forming small germinal centers, are another typical feature of LEP (**Fig. 40-13A** and **B**) but not of SPTCL. The proliferation rate as detected by Ki67 tends to be lower in LEP than in SPTCL. (**Fig. 40-13F**). Evidence of a clonal rearrangement of the TCR genes supports a diagnosis of SPTCL and should be sought for confirmation in most cases. Histopathologic differential diagnostic features between SPTCL and LEP are summarized in **Table 40-2**. Rare cases of MF presenting with subcutaneous lesions usually show a CD4-positive phenotype, in contrast to the CD8-positive one of SPTCL. The presence of positivity for EBV as detected by Epstein-Barr encoding region (EBER) in situ hybridization excludes the diagnosis of SPTCL. Similarly, strong expression of CD30 should prompt consideration for anaplastic large cell lymphoma.

Primary Cutaneous CD4-Positive Small/Medium T-Cell Lymphoproliferative Disorder

Definition

This lesion is characterized by a proliferation of small to medium-sized T-cells with a T follicular helper (TFH) phenotype within the dermis, sometimes with involvement of the subcutaneous fat.[1,2] Since the first description by Friedmann and colleagues in 1995,[47] this lymphoproliferative disorder has been the subject of numerous debates and controversial interpretations, and there is still no consensus regarding the underlying biology and pathogenesis of this lesion. Though evidence of T-cell clonality initially suggested that it was a neoplasm, the localized nature of the process and its excellent prognosis has pointed toward an atypical reactive or antigen-driven immune response for most cases.[48-50]

At the present state of knowledge, it is yet unclear whether cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder represents a subtype of CTCL, a lymphoma precursor, or a fully benign, reactive condition (pseudolymphoma). Patients presenting with solitary lesions located on the head and neck area, who represent most of the reported cases, have an invariably good prognosis and the term LPD reflects this benign clinical behavior.

Synonyms and Related Terms

The same term is used in all contemporary classification systems: ICC (2022); revised WHO 4th edition (2017), and proposed WHO 5th edition (2022)

FIGURE 40-14 Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder. Solitary erythematous tumor on the cheek.

Epidemiology

Patients are adults or elderly individuals, and there is no clear-cut gender predilection. Rarely, children may be affected.[48,49]

Etiology

Etiologic factors are not known, but the absence of recurrent genomic aberrations suggests an abnormal immune reaction rather than a neoplasm.[50]

Clinical Features

Patients present usually with solitary reddish or purple tumors, commonly located on the face and neck or upper trunk (**Fig. 40-14**). Patients with multiple tumors have been reported in the literature, but many of these cases may represent a different entity (probably peripheral T-cell lymphoma, not otherwise specified [NOS]). Ulceration is uncommon. Spontaneous resolution after incisional biopsy may be observed.

Morphology

Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder is characterized by a dense, lymphoid infiltrate within the entire dermis, often involving the superficial part of the subcutaneous fat (**Fig. 40-15A**). Cytomorphology shows a predominance of small to medium-sized lymphocytes with mildly pleomorphic nuclei (**Fig. 40-15B**). Larger immunoblastic cells, when present, are few in number (less than 20%). Epidermotropism is usually absent, and prominent epidermotropism rules out the diagnosis. Many reactive cells are commonly found admixed with the neoplastic ones (lymphocytes, histiocytes, eosinophils, sometimes plasma cells). A granulomatous reaction can be observed in a proportion of the cases. Reactive germinal centers can be present within B-cell nodules.

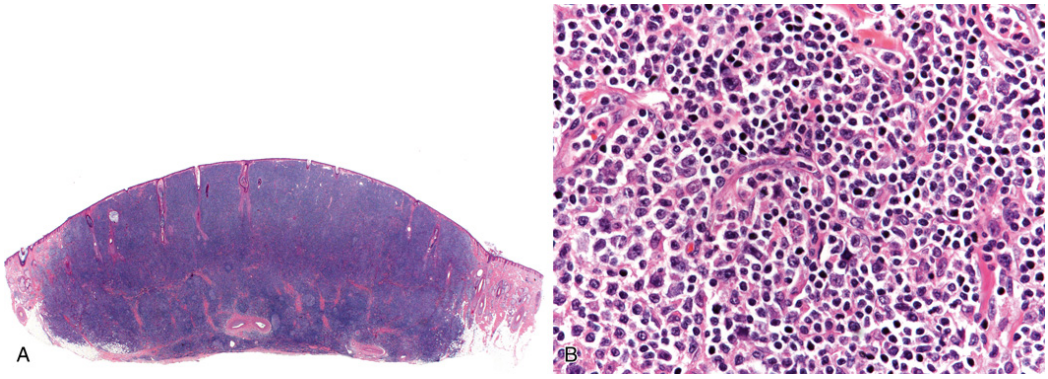

FIGURE 40-15 Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder.A, Dense, nodular infiltrate of lymphocytes within the dermis and subcutaneous fat. **B,** Small to medium-sized lymphocytes predominate.

Immunophenotype

Neoplastic cells show an αβ T-helper phenotype ($CD3^+$, $CD4^+$, $CD5^+$, $CD8^-$, TIA-1^-, $\beta F1^+$, $TCR\gamma^-$; **Fig. 40-16A** and **B**). Staining for CD30 is negative or limited to a small minority of cells. Admixed reactive B lymphocytes are commonly found (**Fig. 40-16C**), sometimes in follicular aggregates. Ki-67 is usually moderately expressed (**Fig. 40-16D**). PD-1 and other TFH markers (CXCL13, ICOS, BCL6, or CD10) are commonly expressed (**Fig. 40-16E**).[49,51]

Genetics

Molecular analysis of the TCR gene rearrangement shows monoclonality of T lymphocytes in the majority of the cases. To date, at least on unilesional lesions, genetic aberrations are rarely found.[50] Only one case was identified with a *DNMT3A* mutation,[52] a finding

that might point toward underlying clonal hematopoiesis in some patients.[53]

Clinical Course

Patients with solitary lesions have an excellent prognosis,[48,54-59] and cases associated with progression are almost invariably those showing multiple lesions at presentation.[60] Patients with lesions confined to the legs or with bulky disease may have a more aggressive course, but they may correspond to other type of lymphomas, e.g., primary cutaneous peripheral T-cell lymphoma, NOS (PTCL, NOS).[61]

Differential Diagnosis

Primary cutaneous acral CD8-positive T-cell lymphoproliferative disorder may be clinically indistinguishable from cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder, but it presents with more monomorphous infiltrates morphologically and with positivity for CD8 and cytotoxic proteins phenotypically. Primary cutaneous PTCL, NOS is usually characterized by multiple lesions and by more profound phenotypic aberrations; in addition, despite CD4 positivity, many cases display expression of cytotoxic markers. Differentiation of primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder from MF may be difficult without correlation with the clinical picture; in general, presence of many reactive cells is uncommon in tumors of MF. The differential diagnosis also includes primary cutaneous marginal zone lymphoma. Some cases even have ambiguous genetic findings with identification of clonal populations of both T cells and B cells by

polymerase chain reaction (PCR) of IG and TCR genes.[50,62,63] As previously mentioned, differentiation of cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder from reactive conditions may be impossible. It has been suggested that at least some of these cases (particularly those presenting with solitary lesions on the head and neck area) are an antigen-driven clonal expansion of T cells that is benign in nature.

Primary Cutaneous Acral CD8-Positive T-Cell Lymphoproliferative Disorder

Definition

Primary cutaneous acral CD8-positive T-cell lymphoproliferative disorder (pcACD8TCLPD) is characterized by skin infiltration of atypical clonal medium-sized CD8-positive lymphocytes. Clinically, the tumor was initially described in acral sites,[64] particularly ear and nose localization, and is characterized by a good prognosis.[64-68]

Synonyms and Related Terms

Primary cutaneous acral CD8-positive T-cell LPD (ICC 2022)
Primary cutaneous acral CD8-positive T-cell lymphoma (WHO 4th edition 2017)
Primary cutaneous acral CD8-positive LPD (proposed WHO 5th edition, 2022)

Epidemiology

The disease affects adults, with a male predominance (male-to-female ratio 3.2:1). The median age is around 56 years.[69] Only one

suspected case was reported in an adolescent.[70]

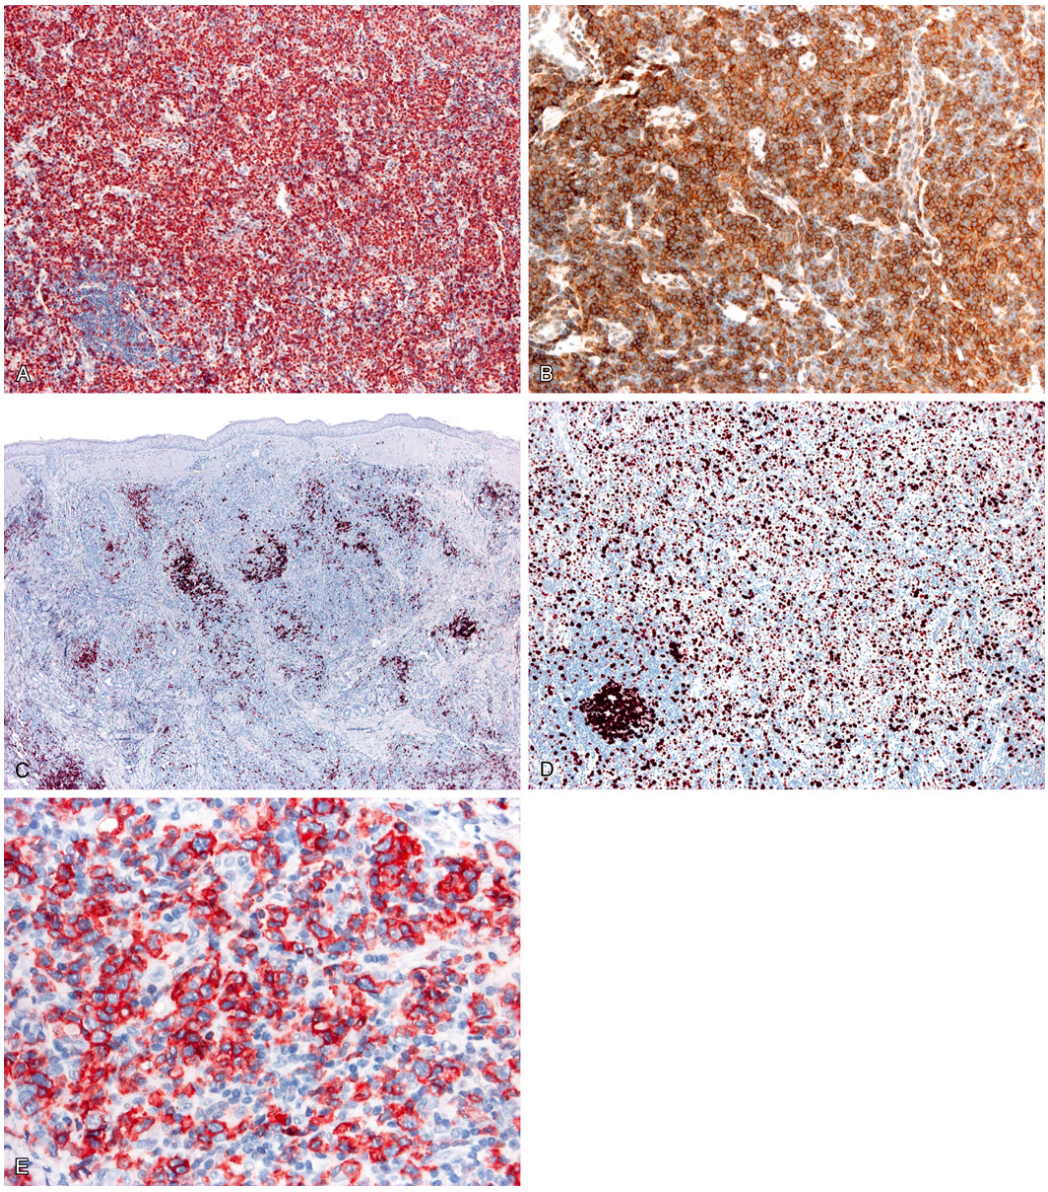

FIGURE 40-16 Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder.Predominance of lymphocytes positive for CD3 **(A)** and CD4 **(B)**. **C,** Note several B lymphocytes with some small nodules (CD20). **D,** Staining for Ki67 demonstrates high proliferation of the cells; note a reactive germinal center showing strong

nodular positivity. **E,** Most T lymphocytes positive for PD-1.

Etiology

It is yet unclear whether this peculiar cutaneous cytotoxic lymphoid proliferation represents a reactive process (pseudolymphoma), a phenotypic variant of cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder, or a distinct entity of CTCL. A local trigger agent may be suspected, but to date, none has been identified. A case presumedly induced by gold earrings has been published.[71] The postulated normal counterpart is a skin-homing CD8-positive T cell. However, similar cases in terms of morphology, phenotype, and clinical outcome have also been described in the gastrointestinal tract (see **Chapter 37**) and genital tract,[72] suggesting the existence of rare lymphomas arising from tissue-resident CD8-positive memory T cells.

Clinical Features

The skin lesion is most often a unique erythematous nodule or papule of 0.5 to 2 cm in diameter. An erythematous and/or squamous plaque measuring up to 5 cm can be seen, most frequently on the feet. Lesions should not be ulcerated (see differential diagnosis). There is generally a history of slow growth over several weeks or months, with a median duration of 19 months.[69] The most frequent site is the ears (two-thirds of the cases), followed by the nose and feet. Eyelids, hands, arms, and legs are sites that have also been reported. Occasionally, lesions are multiple[68] and particularly

bilateral for ears[64,66] and feet.[73] Rare cases have been identified with more disseminated disease (unpublished observation).

Morphology

Histologic features are very typical. The skin biopsies show a dense and diffuse dermal infiltration by very monotonous medium-sized atypical lymphoid cells with irregular and folded nuclei and small nucleoli[64] (**Fig. 40-17A**). Mitoses and apoptotic figures are absent or very rare. A rare case with signet ring cell morphology has been reported.[74] Some reactive B-cell lymphoid aggregates of follicles may be seen within the atypical infiltrate. Plasma cells, neutrophils, or eosinophils are absent or very rare. Granulomatous reaction is absent. The epidermis is most often spared with a grenz zone, particularly on nodular lesions. Infiltration of superficial dermis, with or without minimal epidermotropism, may be seen, particularly in thicker plaques.[68,75] Skin appendages are always spared. Angiotropism can occasionally be seen, but never angiodestruction or necrosis. The proliferation frequently involves the underlying subcutaneous tissue.

Immunophenotype

By definition, tumor cells express CD8 (**Fig. 40-17B**), and they always express CD3, TIA-1, and βF1. TIA-1 displays a very characteristic Golgi dot-like staining (**Fig. 40-17C**). However, Granzyme B and perforin are typically negative. In the large majority of the cases, CD68 is also positive, displaying as does TIA-1 a Golgi dot-like staining (**Fig. 40-17D**), which is considered by some authors to be helpful in differential diagnosis.[76] CD30 is always

negative. Rare co-expression of CD4 may be seen, and CD2, CD5, and CD7 are usually expressed. CD99 is usually positive, but this is not a specific finding (**Fig. 40-17E**). CD56, CD57, and TdT are negative, as are TFH markers (CD10, BCL6, PD1, CXCL13).[68] Proliferative index with Ki-67 staining is usually low (<10%). If the Ki-67 is greater than 50%, other CD8-positive cutaneous lymphomas should be considered. B cells are generally not abundant, and LMP1 and EBER are negative.

Genetics

The neoplastic T cells show clonal TCR gene rearrangements. Specific genetic abnormalities have not yet been described.

Clinical Course

Most cases do not relapse after treatment. Treatment consists of surgical excision or local radiotherapy. Systemic chemotherapy is not indicated. Spontaneous regression has been noted after biopsy. Recurrences in cutaneous sites occur in around 20% of cases, but extension beyond the skin is very rare.[77]

Differential Diagnosis

The differential diagnosis includes primary cutaneous CD8-positive PTCL, NOS and cutaneous CD8-positive lymphoproliferative disorders associated with congenital or acquired immunodeficiency, usually common variable immune deficiency (CVID).[78] Unlike pcACD8TCLPD, most cutaneous CD8-positive T-cell lymphomas are clinically aggressive with a cytotoxic T-cell phenotype. In addition, a

CD8-positive T-cell phenotype can be seen in some cases of MF, particularly in the pediatric age group.[79,80]

Other Types of Cutaneous T-Cell Lymphoma

Besides the four entities mentioned in the preceding sections, other subtypes of CTCL deserve a brief discussion.

Primary Cutaneous T-Follicular Helper–Cell Lymphoma and Cutaneous Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) is a systemic form of T-cell lymphoma with a TFH phenotype.[49,51] A skin rash is a common finding, and in rare cases, a skin biopsy may be the initial diagnostic procedure.[81] The TFH phenotype is characterized by positivity of at least three markers of TFH lymphocytes (PD1, ICOS, CXCL13, CD10, BCL6). In addition, a TFH phenotype has been observed in conventional types of CTCL such as MF or Sézary syndrome, among others.[82] At present, it is not clear whether a primary cutaneous TFH-cell lymphoma exists as an entity distinct from other types of CTCL.

Cutaneous Intravascular NK/T-Cell Lymphoma

Most cases of intravascular large cell lymphoma have a B-cell phenotype, but T-cell and NK-cell phenotypes have been reported in rare instances.[83-86] In contrast to intravascular large B-cell lymphoma, intravascular large NK/T-cell lymphoma (IVLNKTCL) is commonly associated with EBV infection.[83,84]

Neurologic symptoms as a sign of involvement of the central nervous system are commonly present. Histology shows a proliferation of large lymphocytes confined to dilated blood vessels within the dermis and subcutaneous tissues. Lymphatic vessels are not affected. The malignant cells are large with scant cytoplasm and often with prominent nucleoli. Neoplastic cells in IVLNKTCL express CD2, CD3, and cytotoxic proteins but are commonly negative for CD5. CD56 is positive in the majority of cases, whereas βF1 is usually negative. Molecular analysis of the TCR gene rearrangement reveals monoclonality in approximately one-third of cases (the negative ones possibly representing those with an NK-cell phenotype). The course is very aggressive.

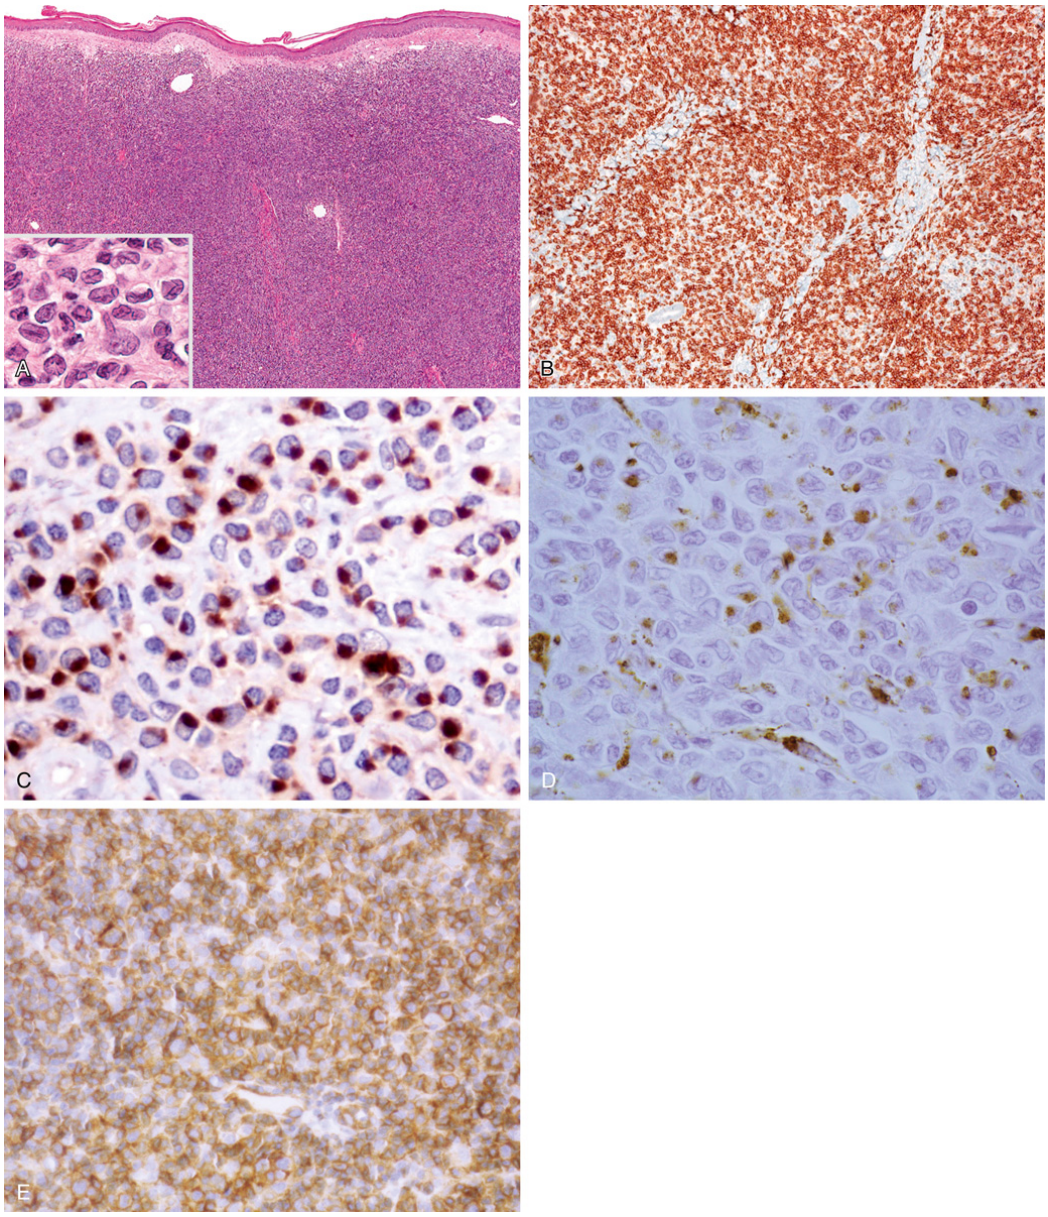

FIGURE 40-17 Primary cutaneous acral CD8-positive T-cell lymphoproliferative disorder.A, Dense, monomorphous lymphoid infiltrate in the dermis; note Grenz zone below an unaffected epidermis and *(inset)* pleomorphic nuclei of neoplastic cells. **B,** Strong positivity for CD8. **C,** Strong positivity for TIA1 (Golgi dots).

D, Variable positivity for CD68 (Golgi dots). **E,** Strong positivity for CD99.

Phenotypic analyses allow the distinction of IVLNKTCL from the more common B-cell variant of intravascular large cell lymphoma. IVLNKTCL should also be differentiated from benign conditions such as intralymphatic histiocytosis and benign intralymphatic proliferation of T-cell lymphoid blasts.

Benign intralymphatic proliferation of T-cell lymphoid blasts has been observed in the skin at sites of previous trauma, within hemangiomas, within endometrial polyps, and in association with appendicitis.[87-92] In contrast to IVLNKTCL, a proliferation of large T lymphocytes in this peculiar condition is observed within lymphatic vessels rather than within blood vessels, and large lymphoid cells are also present outside of the vessels admixed with inflammatory infiltrates. Finally, IVLNKTCL should be differentiated from intralymphatic CD30-positive ALCL.[93,94]

Three other rare types of cutaneous NK/T-cell lymphoma (hydroa vacciniforme lymphoproliferative disease; cutaneous extranodal NK/T-cell lymphoma, nasal-type; and adult T-cell leukemia/lymphoma) are discussed elsewhere (**Chapter 29** and **32**).

Primary Cutaneous Peripheral T-Cell Lymphoma, Not Otherwise Specified

All cases of PCTL that do not fit within the definition of a specific PCTL entity are referred to as primary cutaneous PCTL, NOS. To be able to exclude a specific entity, one needs an adequate sampling of the lesion. A punch biopsy may be not enough. In addition, the

specimen must be examined in conjunction with a thorough clinical history. By definition, PCTL, NOS is heterogeneous clinically and pathologically.[95] In one study, the majority of patients were male (75%), with a medium age of 66.5 years. Clinical lesions were solitary or multiple. When solitary, they were most frequently located on the legs. Histology was variable in terms of morphology of the tumor cells and the presence of reactive cells such as eosinophils, histiocytes, or plasma cells. Frequent aberrant phenotypes such as CD4-negative/CD8-negative or CD4-positive/CD8-positive were found. An aberrant expression of CD20 by tumor cells was found in 18% of the cases. Globally, the prognosis was very poor independently of age, gender, clinical presentation, and CD4/CD8 phenotype.

Pearls and Pitfalls

- Epidermotropism is a pattern that may be encountered in different types of cutaneous lymphoma.
- A diagnostic biopsy should be sufficient to allow for detailed assessment of the morphology and immunophenotype.
- Sufficient material to allow for assessment of clonality and the genomic profile may be required for accurate diagnosis.
- Involvement of subcutaneous fat may be encountered in different types of cutaneous lymphoma.

- Teach surgeons to avoid putting the biopsy specimens on gauze; drying artifacts occur quickly in skin specimens, particularly in small punch biopsies.

Classification of Precursor Lymphoid Neoplasms

Precursor lymphoid neoplasms, often referred to as acute lymphoblastic leukemia (ALL) or lymphoblastic lymphoma, are of either B-cell or T-cell origin. Depending on the cell of origin, these neoplasms are subdivided into B-lymphoblastic leukemia/lymphoma (B-ALL) or T-lymphoblastic leukemia/lymphoma (T-ALL), which may also be abbreviated “B-LL” or “T-LL,” respectively. The distinction between lymphoma and leukemia is somewhat arbitrary. If there is significant blood or bone marrow involvement, then the term *leukemia* is used. If the tumor primarily presents at an extramedullary site with little or no blood or bone marrow involvement, then the term *lymphoma* is preferred. Conventionally, bone marrow involvement by 25% or more blasts has been used as the cutoff between leukemia and lymphoma. The majority of precursor lymphoid neoplasms that

present as leukemia are derived from precursor B cells, and the majority of those that present as tumor masses possess a precursor T-cell phenotype. In practice, the leukemic and lymphomatous presentations of both B-ALL and T-ALL are considered biologically equivalent, and it is generally conceded that this distinction bears little clinical significance. However, distinguishing precursor B-cell from precursor T-cell neoplasms is important because these tumors are biologically and clinically distinct. As such, they are discussed separately.

B-Cell Lymphoblastic Leukemia/Lymphoblastic Lymphoma

Definition

B-ALL is a clonal disorder of hematopoietic precursors with evidence of early B-cell differentiation. The disease is characterized by the presence of a proliferating population of blasts, with minimal morphologic evidence of differentiation. Defining these tumors generally requires immunophenotypic demonstration of B-cell lineage antigen expression. For example, more than 95% of cases express CD19 and HLA-DR.[1] Further, nearly all show clonal rearrangement of the immunoglobulin heavy chain (IGH) gene.[2,3] Unlike most acute myeloid leukemias, a specific blast percentage in the marrow is not required for a formal diagnosis of B-ALL. Marrow-based disease with a low blast count is rare, and the diagnosis should be made with caution in specimens with <20% blasts.

Synonyms and Related Terms

None.

Epidemiology

Overall, ALLs are the most common malignancy in children, accounting for about 80% of childhood leukemias but only about 20% of adult acute leukemias. Most cases occur in children younger than 6 years, and the

majority are B-ALL.[4] The peak incidence is approximately four to five cases per 100,000 children between 2 and 5 years of age; the incidence decreases thereafter until 50 years of age, when it begins to climb slightly again. B-ALL incidence differs based on self-identified race: it affects Whites and Hispanics more commonly than Blacks, and Hispanic children have a higher incidence of ALL[5,6] and a higher relapse rate than do White children.[7] Lymphomatous presentations of B-ALL (B-LBL) are less common than lymphomatous presentations of T-ALL (T-LBL), with B-LBL accounting for only about 10% of lymphoblastic lymphomas. B-LBL is also a disease of young individuals, with the majority of cases occurring in those younger than 20 years.[8,9]

Etiology

The etiology of B-ALL is unknown. A number of studies have suggested a prenatal origin of the genetic events predisposing to the development of leukemia; others have demonstrated the presence of clone-specific antigen receptor gene rearrangements in infants, consistent with an in utero origin of at least a portion of childhood ALLs.[10,11] Further, identical leukemia-specific translocations and antigen receptor gene rearrangements have been documented in monozygotic twins with B-ALL.[12] However, these findings are thought to represent somatic mutations occurring in one twin and shared via in utero circulation rather than constitutional genetic lesions. Although the specific environmental and genetic factors that predispose to B-ALL are not well defined, several factors, such as exposure to ionizing radiation, germline variants including mutations in *PAX5* and *ETV6,* and certain genetic diseases such as Down syndrome have been associated with the development of B-ALL.[13-15] Studies have also shown that single-nucleotide polymorphisms (SNPs) of several genes, including *GATA3, ARID5B, IKZF1, CEBPE,* and *CDKN2A/B,* are associated with susceptibility to B-ALL.[16,17] Disease in these patients has a relatively poor outcome, and a disproportionate percentage are adolescents and young adults. One of these SNPs (rs3824662) is more common in Hispanics[18] and has been suggested to account, in part, for the poorer outcomes seen in this group relative to White patients. However, true

familial ALL is rare, with kindreds described having mutations in *PAX5, ETV6,* and *TP53*.[19-21]

Also, rare cases of B-ALL after chemotherapy have been documented; these often possess rearrangements or amplification of the homeotic regulator mixed lineage leukemia *(MLL)* gene (now called *KMT2A*) on chromosome 11q23.3.[22,23] Interestingly, patients treated with lenalidomide (for plasma cell neoplasms) have an increased risk of secondary B-ALL. Full characterization of lenalidomide-associated B-ALL is ongoing, but this entity tends to present with new-onset cytopenias, low-level marrow involvement, and a relatively favorable prognosis, with some patients reported to respond to withdrawal of lenalidomide alone.[24-26]

Clinical Features

The typical clinical presentation of B-ALL (**Box 41-1**) relates to the development of cytopenias secondary to the replacement of normal bone marrow by leukemic blasts. Clinical manifestations include weakness and pallor caused by anemia, petechiae, and bruising secondary to thrombocytopenia and fever despite granulocytopenia. It is important to note that patients with B-ALL may present with low, normal, or elevated peripheral white blood cell counts, and circulating blasts may be very rare. Thus, patients with unexplained pancytopenia may warrant a bone marrow examination to exclude leukemia. In addition, hepatosplenomegaly or lymphadenopathy may be present at diagnosis, and there may be organ dysfunction caused by leukemic infiltration. Bone or joint pain is also common, particularly in children, and is a result of intramedullary growth of the leukemic cells. B-LBL typically presents with skin or lymph-node involvement with or without peripheral blood or bone marrow involvement, and has infrequently been reported to present as lytic bone lesions.[8,27] In contrast to T-LBL, B-LBL rarely involves the mediastinum.

Morphology

The morphologic examination of peripheral blood or bone marrow remains an essential part of the initial diagnosis of ALL. Blasts in B-ALL can be heterogeneous. Previous classification schemes attempted to subdivide B-ALL on the basis of cytologic features, including nuclear-to-cytoplasmic ratio, nucleoli, nuclear membrane contours, and cell size. However, subdividing B-ALL on the basis of morphology alone has no significant prognostic value and has been supplanted by cytogenetic and molecular subclassification. Nevertheless, recognition of lymphoblasts is important to initiate the appropriate diagnostic evaluation. On a peripheral blood or bone marrow smear, lymphoblasts range from small, round blasts with high nuclear-to-cytoplasmic ratios, relatively condensed chromatin, and inconspicuous nucleoli to larger cells with an increased amount of blue-gray to blue cytoplasm, irregular nuclei with dispersed chromatin, and variably distinct nucleoli. Cytoplasmic vacuoles may be present and can be seen in *MYC*-rearranged B-ALL and *MEF2D*-rearranged B-ALL.[28]

Box 41-1 Major Clinical and Diagnostic Features of Acute Lymphoblastic Leukemia

- Increased lymphoblasts in bone marrow or peripheral blood; no absolute threshold for diagnosis, but rarely <10% in marrow
- Immunophenotypic evidence of either early B (~80%) or early T (~20%) differentiation
- Absence of significant myeloid differentiation
- Anemia, thrombocytopenia, and granulocytopenia (common)
- Clinical features that include fatigue, bleeding, bone pain, fever, lymphadenopathy, organomegaly, and central nervous system involvement

Several morphologic variants of B-ALL have been described. The first, so-called “hand-mirror–cell leukemia,” in which blasts display a distinctive morphology characterized by the presence of an asymmetric cytoplasmic projection called a *uropod,* is of historical interest[29] but of no biological or clinical significance. The second and less common morphologic variant is granular B-ALL. Awareness of this variant is important because the lymphoblasts may be confused with myeloid blasts on morphologic evaluation. In this variant, the blasts contain azurophilic cytoplasmic granules that do not contain myeloperoxidase but can contain acid phosphatase or acid esterase activity, suggesting a lysosomal origin.[30] These cases may not show the increased right-angle side scatter that is characteristically seen in flow cytometric analysis of myeloid blasts that contain abundant granules. Rarely, cases of B-ALL may be associated with peripheral blood eosinophilia that is so marked that it virtually obscures the lymphoblasts. This unusual manifestation is often associated with the chromosomal abnormality t(5;14) (discussed later in this chapter). B lymphoblasts in the setting of eosinophilia may also be seen in “myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions” (see **Chapter 50**).

The cytomorphology of B-ALL that presents as both leukemia and lymphoma is indistinguishable, and the distinction between the subtypes is based on the distribution of tissue involvement. In B-lymphoblastic leukemia, the bone marrow is almost always hypercellular, with replacement of normal marrow elements by a diffuse infiltrate of immature cells (**Fig. 41-1**). High-power examination reveals morphologic variability similar to that observed on smear preparations, ranging from small blasts with fine chromatin and inconspicuous nucleoli to more heterogeneous cells with irregular nuclei and more abundant cytoplasm. Occasionally, tingible body macrophages accompany the infiltrate, imparting a starry-sky appearance; however, the tingible body macrophages are usually not as abundant as in Burkitt lymphoma and may occur only focally. With leukemic presentations, there can be significant organ involvement, with the liver, spleen, kidneys, gonads,

and central nervous system (CNS) being common sites. B-LBL is diagnosed when there is an extramedullary tumor composed of lymphoblasts, with less than 25% lymphoblasts in the blood or bone marrow. Lymphomatous presentations are found most often in extranodal sites, most commonly skin or bone, and often involve the head and neck in children. Lymph nodes are less commonly involved and may demonstrate a paracortical distribution, with preservation of follicles. Hepatic involvement is typically sinusoidal, and splenic disease involves the red pulp.

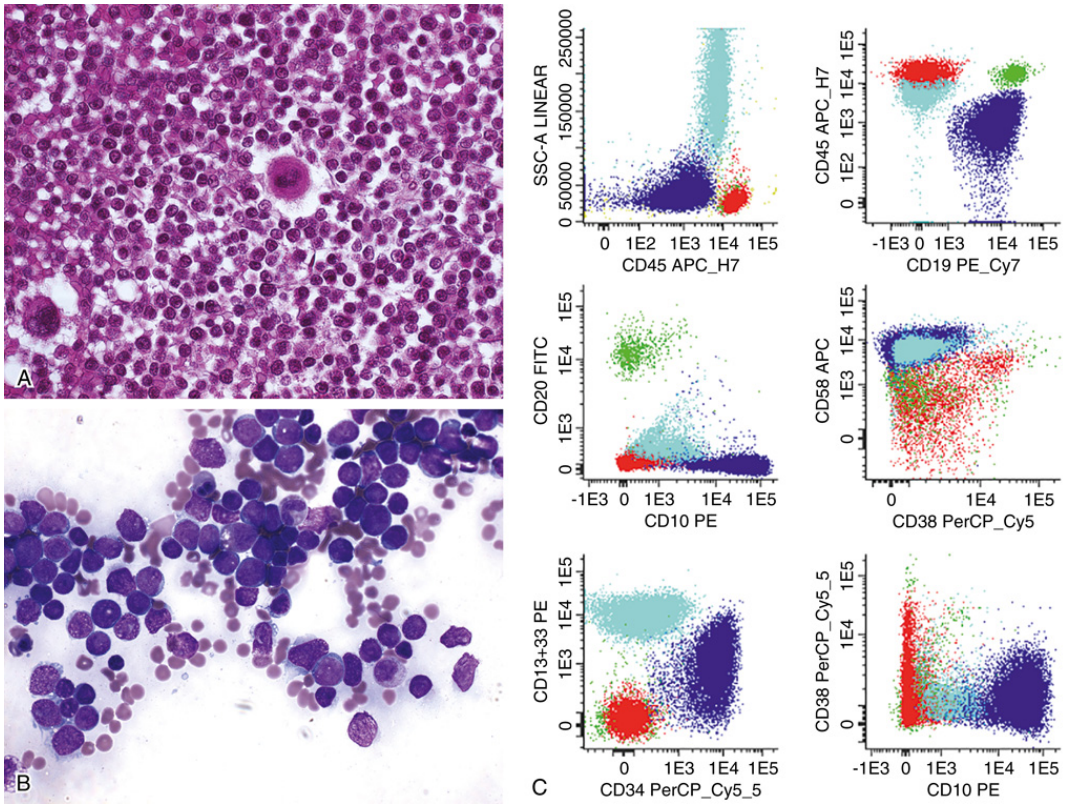

FIGURE 41-1 B-cell acute lymphoblastic leukemia (ALL).A, Bone marrow infiltrated by an interstitial immature lymphoblast population. **B,** Accompanying bone marrow aspirate shows an increase in immature blasts. **C,** Multiparametric flow cytometry demonstrates the blasts *(dark blue)* to be CD45-dim, $CD19^{+}$, $CD34^{+}$, $CD10^{+}$, CD58-bright, CD38-low, and $CD20^{-}$, with variable aberrant myeloid antigen expression. Normal granulocytes *(cyan)*, B cells *(green)*, and T cells *(red)* are also present.

Immunophenotype

B-ALL is defined by evidence of B-cell differentiation. (**Fig. 41-1C**). B lymphoblasts are the neoplastic counterpart of normal precursor B cells (hematogones), which exist in variable numbers in the bone marrow. Hematogones undergo a reproducible pattern of antigen expression during

normal B-cell differentiation. In contrast, B-ALL almost always demonstrates an aberrant antigen profile that is incompatible with normal B-cell differentiation, thus permitting a distinction between malignant and reactive precursor B cells.[31] Nearly all cases of B-ALL express CD19, cytoplasmic CD79a, terminal deoxynucleotidyl transferase (TdT), and HLA-DR. CD10 is present in most, but not all, cases. Surface expression of CD22 is often weak but expressed in almost all cases. CD20 is usually variably expressed, although individual cases can range from complete absence of CD20 to moderately intense and uniform expression of this antigen. Cytoplasmic CD22 is a very sensitive marker for B-ALL, but it may also be detected in some cases of acute myeloid leukemia (AML)[32] in conjunction with possible weak expression of CD19 and TdT. CD79a has been suggested as both a sensitive and a specific marker of B-lineage ALL, but it is not specific for B-ALL because it is also seen in a significant fraction of T-ALLs.[33] Outside of AML with t(8;21), which expresses many B-lymphoid markers, PAX5 is highly specific for B-cell lineage.[34] Although IGH gene rearrangements occur relatively early in B-cell development and B-ALLs show clonal rearrangements by molecular analysis, most fail to express surface immunoglobulin. Low levels of surface immunoglobulin are, however, expressed in a minor subset of B-ALL cases.

Additional antigenic markers have been useful in characterizing B-ALL, with an emphasis placed on those that are suitable for distinguishing normal and leukemic precursors. These include CD24, CD34, CD123, CD73, CD304, CD81, CD58, CD38, and CD9, all of which are expressed in a significant fraction of cases, often at abnormal levels.[1,35-37] It should be noted that, among B-cell neoplasms, CD34 is uniquely expressed in lymphoblastic lesions and has particular significance in classifying these lesions as precursor-derived. TdT expression is also characteristic of immature B-lymphoblastic lesions, although it is not always present and has been very rarely reported in high-grade or transformed mature B-cell lymphomas.[38-41] CD45, or the leukocyte common antigen, is not expressed in approximately 10% to 20% of cases of B-ALL, and in the remaining cases, it typically shows

lower levels of expression than those found in normal B precursors.[42,43] CD99, more commonly thought of as a marker of Ewing's sarcoma, is also expressed by most hematopoietic tumors that express TdT.[44-46] Thus, expression of CD99 coupled with lack of CD45 expression does not exclude a diagnosis of B-ALL. Finally, expression of myeloid antigens, including CD13, CD33, and CD15, is found in about 10% to 15% of childhood B-ALLs[47] and in approximately 25% of adult cases.[48,49] However, the myeloid-blast–associated antigen CD117 is only very rarely present in B-cell ALL and should prompt consideration for AML with aberrant expression of B-cell antigens or B/myeloid mixed-phenotype acute leukemia (MPAL).[50] The routine evaluation for myeloperoxidase (MPO) expression in B-ALL can be problematic because otherwise typical cases of B-ALL have occasionally been shown to express low levels of MPO,[51-54] and this should not automatically result in a diagnosis of MPAL in the absence of other criteria.

Genetics and Molecular Findings

Nearly all cases of B-ALL have rearrangement of the IGH gene.[3] However, IGH gene rearrangement can also occur in both T-ALL and AML, limiting the utility of this test as a marker of lineage commitment. Immunoglobulin light chain (IGL) rearrangement can also occur and is thought to be a more specific marker of B-cell differentiation.

B-ALL is increasingly defined by specific genetic abnormalities that are associated with specific phenotypes and clinical behaviors (**Table 41-1**), many of which are incorporated into the International Consensus Classification (ICC) and the proposed World Health Organization (WHO) 5th edition of the Classification of Tumours of Haematopoietic and Lymphoid Tissues.[55-57] Initially, classical cytogenetic studies were mostly used to subclassify B-ALLs, and this method was subsequently supplemented by fluorescence in situ hybridization (FISH) and targeted polymerase chain reaction (PCR). More recently, large-scale studies that use clustering algorithms to correlate RNA-seq based gene expression (GEX) patterns with genetic findings have enabled the identification of multiple new subtypes of

B-ALL. Although detailed discussion of methodology used to identify these lesions is beyond the scope of this chapter, many entities can now be recognized by FISH, multiplex PCR, or standard next-generation sequencing studies, and some have immunohistochemical or flow cytometric surrogates. Whole transcriptome sequencing, or unbiased RNA-seq, is probably the single most robust method that can be used to detect most of these lesions.[58]

The increasingly granular subclassification of B-ALL is significant because some of the identified genetic abnormalities enable targeted therapy. In addition, the prognostic information may be used to identify patients for whom low-intensity therapy will likely be curative, thus avoiding complications of more aggressive treatment. Thus, it is useful to consider these recurrent chromosomal and molecular abnormalities (**Box 41-2**) individually.

Quantitative Chromosomal Abnormalities

It has long been known that hyperdiploidy with greater than 50 chromosomes (sometimes called *high hyperdiploidy*) is a strong predictor of durable response to therapy in childhood B-ALL; this entity is recognized and defined similarly by both the ICC and the proposed WHO 5th edition. These patients account for about 25% of childhood B-ALL cases and often possess other favorable features, including lower peripheral white blood cell counts and age between 2 and 10 years.[59,60] However, hyperdiploidy confers a good prognosis independent of these other indicators, and it predicts a favorable response, regardless of peripheral white blood cell count.[61] The good prognosis associated with hyperdiploidy appears to be a result of the addition of specific chromosomes, and in some clinical trials, finding trisomies involving chromosomes 4 and 10 have been used as a surrogate for high hyperdiploidy for treatment assignment.[62] Children with B-ALL having hyperdiploidy with 47 to 50 chromosomes account for 10% to 15% of cases, and these patients do not have the same favorable prognosis.[59]

Table 41-1

Characteristics of B-ALL Entities in the ICC

Diagnosis	Frequency and Clinical Features	Comments
B-ALL with t(9;22)(q34.1;q11.2)/*BCR*::*ABL1*	~5% of children, ~30% of adults; poor prognosis but much improved with TKI therapy. Multilineage type akin to CML in blast crisis, but no antecedent history and typically no splenomegaly	CD19+10+, often with myeloid antigens or CD25; Divided into lymphoid only and multilineage, depending on cells that have Ph chromosome
B-ALL with t(v;11q23.3)/*KMT2A* rearranged	Half of infant ALL; uncommon but seen in all age	Multiple partners, *AFF1* most common. Blasts typically CD19+, CD22-

Diagnosis	Frequency and Clinical Features	Comments
	groups. High WBC and CNS involvement, poor prognosis	dim, CD10–, CD24–, CD15/65+, especially with *AFF4*
B-ALL with t(12;21) (p13.2;q22.1)/*ETV6*::*RUNX1*	25% of childhood ALL, good prognosis; 3% of adults	CD19+, CD10+, CD27+, CD44-low/–, CD9–
B-ALL, hyperdiploid	25% of childhood ALL, good prognosis; uncommon to rare in adults	>50 chromosomes (not triploid or tetraploid), typically simple additions without structural abnormalities
B-ALL, low hypodiploid	Rare, poor prognosis	32–39 chromosomes; *TP53* and *RB1* mutations; *TP53* often germline

Diagnosis	Frequency and Clinical Features	Comments
B-ALL, near haploid	Rare, poor prognosis	24–31 chromosomes; *RAS* and RTK signaling mutations
B-ALL with t(5;14) (q31.1;q32.3)/*IL3*::*IGH*	Rare, poor prognosis	Eosinophilia from upregulation of *IL3*
B-ALL with t(1;19) (q23.3;p13.3)/*TCF3*::*PBX1*	Relatively common, average prognosis if treated appropriately	Pre-B phenotype: CD19+, 10+, CD34– with cytoplasmic mu expression
B-ALL, *BCR*::*ABL1*–like, ABL-1 class rearranged	2%–3% of childhood ALL, higher in adults. Poor prognosis but some patients respond very well to	Rearranged genes include *ABL1, ABL2, CSF1R, LYN, PDGFRA, PDGFRB*

Diagnosis	Frequency and Clinical Features	Comments
	TKI therapy	
B-ALL, *BCR*::*ABL1*–like, JAK-STAT activated	5%–10% of childhood ALL, 25% of adults; poor prognosis	~50% have *CRLF2* rearrangements with overexpression of *TSLPR*, the CRLF2 gene product; *JAK* mutated or rearranged
B-ALL with iAMP21	~2% of childhood ALL, rare in adults. Poor prognosis but intensive treatment improves outcome	Typically detected by *RUNX1* FISH as five or more signals per cell
B-ALL with *MYC* rearrangement	2%–5%, higher in adults and AYA; poor prognosis	May also have *BCL2/6* rearrangements

Diagnosis	Frequency and Clinical Features	Comments
B-ALL with *DUX4* rearrangement	5%–10%, highest in AYA and adult; excellent prognosis	*ERG* and *IKZF1* deletions but still excellent prognosis; CD371 expression an excellent surrogate
B-ALL with *MEF2D* rearrangement	3%–5%; poor prognosis	CD10 low/–; CD38 high; Multiple partners, most common *BCL9*
B-ALL with *ZNF384* rearrangement	5%–10%; highest in AYA	CD10 low/–, myeloid antigen+; common in B/myeloid MPAL. *EP300* most common partner with better prognosis
B-ALL with *NUTM1* rearrangement	2% or less, mostly infants; far better	Multiple partners. Can detect with IHC

Diagnosis	Frequency and Clinical Features	Comments
	prognosis than KMT2A-r	
B-ALL with *HLF* rearrangement	<<1% children, very poor prognosis	*TCF3* most common partner ("t(17;19)"; *TCF4* rare but same poor prognosis
B-ALL with *UBTF*::*ATXN7L3/PAN3,CDX2* ("CDX2/UBTF")	<1%; higher in AYA, female predominance, poor prognosis	Two alterations: gene fusion detectable by PCR; deletion on chromosome 13 and 17, resulting in *CDX2* deregulation
B-ALL with mutated *IKZF1* N159Y	<1%, variable prognosis	Detectable by targeted NGS
B-ALL with mutated *PAX5* P80R	2%–5%, more common in adults; good	Detectable by targeted NGS

Diagnosis	Frequency and Clinical Features	Comments
	prognosis in adults	

ALL, Acute lymphoblastic leukemia; *AYA,* adolescents and young adults; *B-ALL,* B-lymphoblastic leukemia/lymphoma; *CML,* chronic myeloid leukemia; *CNS,* central nervous system; *IHC,* immunohistochemistry; *MPAL,* mixed phenotype acute leukemia; *NGS,* next-generation sequencing; *Ph,* Philadelphia; *RTK,* receptor tyrosine kinase; *TKI,* tyrosine kinase inhibitor; *TSLPR,* thymic stromal lymphopoietin receptor; *WBC,* white blood cell.

Hypodiploidy also occurs, usually cause by the loss of one or more chromosomes, an unbalanced translocation, or the formation of dicentric chromosomes. Unlike hyperdiploidy, hypodiploidy is associated with poor prognosis.[63] In the ICC, hypodiploid B-ALL is formally separated into two different entities: "B-ALL, low hypodiploid" (32-39 chromosomes), and "B-ALL, near haploid" (24-31 chromosomes). The low hypodiploid group is associated with loss-of-function mutations in *TP53* and *RB1,*[64] and could be considered a form of Li-Fraumeni syndrome in that subset of patients that are found to have germline *TP53* mutations.[65] In contrast, near-haploid B-ALL is associated with a different set of mutations, especially *RAS* and receptor tyrosine kinase signaling mutations.[65,66]

Box 41-2 ICC of Acute Lymphoblastic Leukemias

B-Lymphoblastic Leukemia/Lymphoma (B-ALL)

B-ALL with recurrent genetic abnormalities

B-ALL with t(9;22)(q34.1;q11.2)/*BCR*::*ABL1*

With lymphoid-only involvement[a]

With multilineage involvement[a]

T-Lymphoblastic Leukemia/Lymphoma (T-ALL)

Early T-cell precursor ALL with *BCL11B* activation[i]

Early T-cell precursor ALL, not otherwise specified[i]

T-ALL, not otherwise specified

Provisional entity: T-ALL with *TAL1/2* dysregulation[g]
Provisional entity: T-ALL with *TLX1* rearrangement[g]
Provisional entity: T-ALL with *TLX3* rearrangement[g]
Provisional entity: T-ALL with *HOXA* dysregulation[g]
Provisional entity: T-ALL with *LMO1/2* dysregulation[g]
Provisional entity: T-ALL with *NKX2* rearrangement[g]
Provisional entity: T-ALL with *SPI1*-rearrangement[g]
Provisional entity: T-ALL with other *bHLH* alterations[g]
Provisional entity: natural killer (NK) cell ALL[j]

Entities in **bold** are included in the World Health Organization (WHO) proposed 5th edition of the Classification of Tumours of Haematopoietic and Lymphoid Tissues. The WHO has slightly different terminology, not including the cytogenetic translocation terminology, and uses the term "fusion" rather "rearrangement" in the definition.

---

[a] Combined as B-lymphoblastic leukemia/lymphoma with *BCR*::*ABL1* in proposed WHO 5th edition and WHO 4th edition.

[b] B-lymphoblastic leukemia/lymphoma with high hyperdiploidy in proposed WHO 5th edition and WHO 4th edition.

[c] Combined as B-lymphoblastic leukemia/lymphoma with hypodiploidy in proposed WHO 5th edition and WHO 4th edition.

[d] Combined as B-lymphoblastic leukemia/lymphoma with *BCR*::*ABL1*-like features in proposed WHO 5th edition and WHO 4th edition.

[e] Included with B-lymphoblastic leukemia/lymphoma with other defined genetic abnormalities in proposed WHO 5th edition; not included in WHO 4th edition.

[f] Only B-lymphoblastic leukemia/lymphoma with *TCF3*::*HLF* fusion in proposed WHO 5th edition; not included in WHO 4th edition.

[g] Not included in proposed WHO 5th edition or WHO 4th edition.

[h] B-lymphoblastic leukemia/lymphoma with *ETV6*::*RUNX1*-like features in WHO 5th edition; not included in WHO 4th edition.

[i] Combined as early T-cell precursor ALL in proposed WHO 5th edition and WHO revised 4th edition.

[j] Provisional entity in WHO revised 4th edition but deleted from proposed WHO 5th edition.

Another distinct subgroup of B-ALL exhibits intrachromosomal amplification of one copy of chromosome 21 (iAMP21) with at least four copies of *RUNX1* on an abnormal chromosome.[67] iAMP21 is also associated with other characteristic cytogenetic abnormalities, including gain of chromosome X, loss or deletions of chromosome 7, and deletions of *ETV6* and *RB1*. These cases comprise approximately 2% of B-cell ALL cases, tend to affect older children but not adults, are associated with low white blood cell counts at diagnosis, and are commonly associated with CRLF2 overexpression. This abnormality can be most reliably detected by FISH for *RUNX1,* and identification of these patients is critical because iAMP21 has been associated with poor prognosis if intensive chemotherapeutic regimens are not used.[67]

Translocations and Other Molecular Alterations

There are a number of well-characterized chromosomal translocations associated with B-ALL. In children, the most common molecular abnormality is the *ETV6*::*RUNX1* fusion. It is observed in approximately 25% of childhood B-ALL but in only 3% of adult cases.[68] This translocation produces an abnormal fusion protein between the Ets family transcription factor *ETV6 (TEL)* and the DNA-binding subunit of the core binding factor complex RUNX1 *(AML1)*. Both these transcription factors appear to be necessary for hematopoiesis,[69,70] and transduction of the *ETV6*::*RUNX1* fusion protein into mouse hematopoietic stem cells has been shown to induce ALL.[71] It is important to note that detection of this lesion generally requires the use of FISH because there is generally a balanced cryptic t(12;21)(p13.2;q22.1) not apparent when classic karyotyping is used.[72] B-ALLs harboring this translocation often possess a characteristic immunophenotype: expression of CD34, partial expression of CD20, and in particular, little or no expression of

CD9.[73] Also, unlike most other ALLs, they are CD27 positive and CD44 negative or low.[74] The presence of *ETV6*::*RUNX1* confers an improved event-free survival in children,[75] though some have suggested that these patients are at increased risk for late relapse.[76] Although this point remains controversial, the unusual demonstration of clonally identical *ETV6*::*RUNX1* leukemias arising years apart in monozygotic twins has led to the hypothesis that this fusion is an early event in leukemogenesis,[10] which raises the interesting question of whether late relapses might be new second leukemias derived from a dormant leukemic precursor.

In adults, the most frequently observed chromosomal abnormality is t(9;22)(q34.1;q11.2), or the Philadelphia (Ph) chromosome. This translocation, present in about 25% of adult and up to 5% of childhood B-ALL,[68] involves the *ABL1* oncogene on chromosome 9 and the guanosine triphosphate–binding protein BCR on chromosome 22. The resultant fusion protein has abnormal tyrosine kinase activity, leading to disturbances in cell proliferation, survival, and adhesion.[77] Although the BCR::ABL1 fusion protein is also found in chronic myeloid leukemia (CML), in about 70% of cases of *BCR*::*ABL1*-positive ALL, the expressed protein is only 190 kDa rather than the 210 kDa typically seen in CML, reflecting less contribution of the *BCR* gene to the fusion protein.[78] Ph chromosome positivity is associated with a poor prognosis in both children[79,80] and adults,[81] although the availability of tyrosine kinase inhibitors has improved outcome.[82]

The ICC further divides "*BCR*::*ABL1*-positive B-ALL" into two subtypes: "B-ALL with t(9;22)(q34.1;q11.2)/*BCR*::*ABL1* with lymphoid only involvement" (*BCR*::*ABL1*-positive ALL-L) and "B-ALL with t(9;22)(q34.1;q11.2)/*BCR*::*ABL1* with multilineage involvement" (*BCR*::*ABL1*-positive ALL-M). In *BCR*::*ABL1*-positive ALL-M, the target cell for the transformation event is a multipotent progenitor, whereas in *BCR*::*ABL1*-positive ALL-L, the target cell is a later progenitor. *BCR*::*ABL1*-positive ALL-M is akin to CML presenting in lymphoid blast phase (CML-LBP), but it lacks significant splenomegaly and a history of CML characteristic in CML-LPB. In *BCR*::*ABL1*-positive ALL-L, however, the translocation is only seen in blasts.

BCR::*ABL1*-positive ALL-L and ALL-M may be difficult to differentiate at diagnosis when blasts greatly predominate, and cell separation techniques coupled with FISH may be needed to assess which cells harbor the fusion signal.[83] *BCR*::*ABL1*-positive ALL-M may also be suspected when the percentage of cells that are Ph positive is significantly greater than the blast percentage or after therapy when there is a discordance between levels of residual leukemia detected by reverse transcription (RT)-PCR compared with flow cytometry or DNA PCR methods.[83]

Recurrent chromosomal abnormalities involving the *KMT2A* (formerly *MLL*) gene on the chromosome 11q23.3 locus have been observed in B-ALL and have prognostic significance.[84] The most common of these is the rearrangement t(4;11)(q21;q23)/*KMT2A*::*AFF1*. *KMT2A*-rearranged B-ALL can use a large number of different partner genes, the most common alternative of which is *MLLT1* at 19p13. B-ALLs with *KMT2A* rearrangements, especially t(4;11), tend to occur in infants. They often present with high white blood cell counts, organomegaly, and CNS involvement, and patients have a poor prognosis. These lymphoblastic leukemias have a unique phenotype that distinguishes them from other B-ALLs. They characteristically express CD19 but lack CD10 and CD24.[85] They also have a propensity to co-express the myeloid antigens CD15 and CD65,[86] prompting the *mixed lineage leukemia* moniker. Although t(4;11) leukemia confers poor prognosis, there is some controversy as to whether leukemias that use alternative fusion partners with *KMT2A* have an equally poor outcome. B-ALL with *KMT2A* rearrangements are characterized by lineage ambiguity and may present or recur as either B-ALL or B/myeloid MPAL.

TCF3 (formerly *E2A*)::*PBX1/t* (1;19)(q23.3;p13.3) is another well-characterized and relatively common translocation in B-ALL. This leukemia has a characteristic immunophenotype expressing CD19, CD10, homogeneous CD9, and partial CD20 but completely lacking CD34.[87] Although the presence of t(1;19) was once thought to confer poor prognosis, with current intensive therapies, the outcome in these children is comparable to that of patients with similar risk factors.[88,89]

A distinctive subtype of ALL associated with t(5;14)(q31.1;q22.1) is characterized by a marked eosinophilia. This translocation juxtaposes the interleukin-3 *(IL3)* gene with the IGH gene on chromosome 14.[90-92] The lymphoblasts themselves are not morphologically distinctive; however, the eosinophils, which are not part of the neoplastic clone, often show morphologic atypia, including areas of cytoplasmic clearing and abnormal nuclear segmentation. Circulating blasts tend to be infrequent and are often obscured by the eosinophilia, but blasts are more numerous in the bone marrow. Patients with this variant often have symptoms related to the toxic effects of eosinophil degranulation, particularly cardiac disease.

Though most of the common translocations in B-ALL were originally detected via karyotype and are now more typically detected by FISH or PCR, GEX profiling was first used to define a number of new entities, including "B-ALL, *BCR*::*ABL1*-like." This entity was first recognized based on a GEX profile similar to B-ALL positive for Ph but lacking the *BCR*::*ABL1* translocation.[93] This entity was introduced in the revised WHO 4th edition and is retained in the proposed WHO 5th edition; however, the ICC further subclassifies these "*BCR*::*ABL1*-like" cases into three subtypes: *ABL1*-class rearranged, JAK-STAT activated, and not otherwise specified (NOS). Comprehensive identification of these subtypes requires genomic studies, as none of these entities, apart from rearrangement of *CRLF2* in a subset of cases in the JAK-STAT subgroup, shows distinctive immunophenotypic abnormalities.

"B-ALL, *BCR*::*ABL1*-like: *ABL1*-class rearranged" includes fusions between *ABL1, ABL2, CSF1R,* or *PDGFRB* and various partner genes. Identification of this group is particularly important because these cases may respond to tyrosine kinase inhibitors (TKIs) that target *ABL1*.[94] Though *PDGFRB*-r lymphoid neoplasms are typically included in "myeloid/lymphoid neoplasms with *PDGFRB* rearrangement," those presenting as B-ALL are best classified as *BCR*::*ABL1*-like ALL, *ABL1*-class rearranged. The second new subclassification in the ICC is the "B-ALL, *BCR*::*ABL1*-like: JAK-STAT activated" cases. The most common mutations that result in activation of

JAK-STAT pathway signaling are *CRLF2* rearrangements to IGH or *P2RY8,* resulting in overexpression of the gene product TSLPR (thymic stromal lymphopoietin), although this is commonly conventionally referred to as CRLF2 as well. This group also includes cases with *JAK* translocations or mutations. JAK inhibitors are currently in trials for this entity. The third subclass is "B-ALL, *BCR*::*ABL1*-like, NOS," which encompasses heterogeneous alterations of other kinases and cytokine receptors; it should be noted that many have been shown to be responsive to TKIs in preclinical models, particularly kinase rearrangements (*FLT3, FGFR1, NTRK3,* and *PTK2B*). Fusions involving *NTKR3* may show profound responses to TKIs such as larotrectinib.

BCR::*ABL1*-like B-ALL has a poor prognosis overall.[94] Further subclassification of this category may allow for the identification of specific targetable lesions and provide novel therapeutic opportunities for these patients.

Several additional entities characterized by gene fusions are included as specific entities in the ICC and most also in the proposed WHO 5th edition, either explicitly or part of a larger group with miscellaneous genetic abnormalities. Many of these have distinct prognoses. With the exception of "B-ALL with *DUX4*-rearrangement" and "B-ALL with *ZNF384*-rearrangement," which each account for about 5% to 10% of cases, the other entities with defining fusion proteins are rare. B-ALL with double homeobox 4 *(DUX4)*-rearrangement is relatively common in adolescents and young adults. This entity is associated with an excellent prognosis in both children and adults, even in the presence of otherwise poor-risk genetic features.[74] The *IGH*::*DUX4* translocation is inconsistently detected by transcriptome sequencing and is difficult to detect by FISH because of the repetitive nature of both the *DUX4* and IGH loci; however, these cases characteristically show expression of CD371 on flow cytometric analysis.[95] Rearrangements of the transcription factor zinc finger 384 *(ZNF384)* defines a subtype of B-ALL that is most common in children and young adults and has a variable prognosis. Similar to *KMT2A*-rearranged B-ALL, these cases are characterized by

lineage ambiguity and may present as either B-ALL or B/myeloid MPAL.[96] *ZNF384* has numerous fusion partners, most commonly *EP300, TCF3,* and *TAF15,* and the prognosis depends on the fusion partner.[97]

Though *MYC* translocations are more frequently associated with mature B-cell lymphoma, they are also reported in about 4% of adult B-ALL and, rarely, pediatric B-ALL. *MYC*-r B-ALL and *MYC*-r mature B-cell lymphoma are genetically distinct from one another. *IG*::*MYC* positive B-ALL cases are characterized by aberrant VDJ joining in a B cell precursor undergoing VDJ recombination, whereas B-ALLs with *MYC*-r are characterized by unmutated IGVH genes.[98] Accordingly, these entities may be separable via somatic hypermutation studies, with only *MYC*-rearranged (*MYC-r*) mature large B-cell lymphomas exhibiting somatic hypermutation. The clinical presentations of *MYC*-r mature B-cell lymphomas and *MYC*-r B-ALL are also typically very different, with mass lesions in the former and bone marrow replacement in the latter; however, there is some clinical overlap, and definitive distinction requires laboratory studies. CD34 or TdT expression favors a diagnosis of B-ALL, though transformed or aggressive mature B-cell lymphomas can show TdT expression, and a diagnosis of *MYC*-r B-ALL should be avoided in patients with such a history. *MYC*-r B-ALL is associated with a very poor prognosis.

There are other rare fusions included in the ICC, most of which have a poor prognosis, including B-ALL with myocyte enhancer factor 2D *(MEF2D)* rearrangements[99] and B-ALL with *HLF* rearrangement. Another B-ALL subtype, found only in the ICC and referred to as "CDX2/UBTF," harbors two alterations in all cases, namely a fusion oncoprotein-encoding rearrangement *UBTF::ATXN7L3* and a deletion upstream of *FLT3* that results in deregulation of CDX2; both alterations are required to produce leukemia. This subtype also has a poor prognosis. One final B-ALL subtype that is defined by a fusion is NUT midline carcinoma family member 1 *(NUTM1)*-rearranged B-ALL. This subtype typically affects infants and has a relatively favorable prognosis.

Finally, the ICC incorporates two new entities that are defined by point mutations: B-ALL with *PAX5* P80R and B-ALL with *IKZF1* N159Y. B-ALL with a *PAX5* P80R mutation accounts for 2% to 5% of B-ALL cases, is more common in adults, and has a relatively good prognosis. B-ALL with a DNA-binding protein Ikaros *(IKZF1)* N159Y mutation accounts for less than 1% of cases, is more common in adults, and has an intermediate prognosis.

The ICC also includes several provisional entities (**Box 41-2**), one of which is included in the proposed WHO 5th edition classification: "B-ALL, *ETV6*::*RUNX1*-like." These cases share the same GEX profile and CD27-positive, CD44-dim/negative phenotype as B-ALL with *ETV6*::*RUNX1* fusion, but they lack the defining t(12;21)(p13.2;q22.1).

Additional Genetic Lesions

Virtually all cases of ALL harbor additional genetic alterations beyond the driver lesions that define the entity. These are seen across different entities and so are not included in the classification. Many of these, most notably *IKZF1* and *CDKN2A/B* deletions, are commonly associated with poor prognosis; however, as exemplified by the good outcome of patients with *DUX4*-r ALL and *IKZF1* deletions, the significance of specific mutations may be different in different genetic subgroups.[100]

Normal Counterpart

The normal counterpart for the B-lymphoblasts in B-ALL is the normal precursor B cell that resides within the bone marrow. These cells, also known as *hematogones,* are seen with increased frequency in children and tend to decrease with age. However, hematogone content can vary widely, especially during hematopoietic regeneration, and may be significantly increased after umbilical cord blood stem cell transplant.[101] Hematogones possess a very reproducible pattern of antigen acquisition that helps distinguish them from B-ALL. The earliest hematogones express dim CD45 with low right-angle light scatter, CD19, CD10, CD34, CD38, and TdT. These cells lack CD20 and surface immunoglobulin expression and express dim CD22. As the cells

mature, CD20 is acquired, and early antigens such as CD34 and CD10 are lost. Because of the reproducible nature of antigen expression on normal precursor B cells, multiparametric flow cytometry can reliably distinguish normal cells from leukemic precursor B cells in most cases.[102] This principle is routinely applied in monitoring patients with B-ALL for the presence of minimal residual disease (MRD).

Clinical Course

In general, B-cell ALL of childhood has become a disease with a high cure rate, whereas adults with B-cell ALL have a poorer prognosis, in part because the good prognosis lesions of hyperdiploidy and *ETV6*::*RUNX1* are much less common in adults. Use of tyrosine kinase inhibitors to treat *BCR*::*ABL1*-positive B-ALL in both children and adults has resulted in improved outcomes.[82,103] Other promising therapeutic strategies include the application of pediatric chemotherapy to young adults[104]; the use of improved formulations of standard chemotherapeutics such as PEG-asparaginase; and the use of immunotherapeutics such as rituximab and anti-CD22 monoclonal antibodies,[105] bispecific anti-CD19/CD3 antibody therapy,[106,107] and chimeric antigen receptor (CAR) T-cell therapy.[108,109]

Prognosis, however, hinges on the presence or absence of increasingly well-characterized genetic and molecular abnormalities. Children with leukemias harboring the *ETV6*::*RUNX1* translocation or possessing more than 50 chromosomes have a long-term event-free survival rate of 90% or greater. However, those with molecular lesions associated with *BCR*::*ABL1*-like ALL or those with t(4;11) fare much more poorly, and some children with other high-risk features have a long-term event-free survival rate of less than 50%. As noted, many of the more recently recognized entities also have prognostic significance, and most, with the exception of *DUX4*-rearranged ALL, have a poor prognosis.[99] The reason for the different clinical outcomes in these subtypes remains unknown, but new insights into the molecular and cellular biology of these subtypes may help tailor subgroup-oriented therapies. In addition, it is hoped that use of the refined ICC and proposed WHO 5th

edition classification will assist in risk stratification and optimal treatment selection for patients with B-ALL.

Although new prognostically relevant genetic risk factors continue to be discovered, early response to therapy remains the most important prognostic factor. How rapidly a patient clears morphologically evident disease during induction predicts long-term outcome,[110] but the presence of MRD at levels below that of morphologic detection is an even stronger prognostic factor,[111-113] and such measurements play a vital role in risk stratification and management of patients with ALL. MRD may be measured by flow cytometry[111,113] (**Fig. 41-2**) or by PCR[112] directed against antigen receptor genes, although the latter technique is more cumbersome and expensive because it requires the production of patient-specific probes or primers. Thresholds of 0.01% of blasts detected by flow cytometry at the end of induction therapy are typically used to identify patients in need of enhanced treatment, but other thresholds and other timepoints are used for treatment assignment with PCR-based MRD. Next-generation sequencing[114] strategies are even more sensitive, potentially easier to standardize, and are becoming more routinely used for MRD analysis in ALL. There is some evidence that this enhanced sensitivity can identify additional patients at risk for relapse.[115]

Differential Diagnosis

The differential diagnosis generally includes a number of hematopoietic tumors that may possess blast-like morphology and a small number of undifferentiated or primitive non-hematopoietic tumors (Tables **41-2** and **41-3**). Immunophenotypic analysis is typically required to distinguish among these neoplasms.

T-Cell Lymphoblastic Lymphoma/Lymphoblastic Leukemia

Definition

Like precursor B-cell tumors, T-cell lymphoblastic lesions are clonal hematopoietic stem cell disorders, but they are characterized by an immature T-cell, rather than B-cell, phenotype. Operationally, identification of T-cell antigen expression is required for the diagnosis of T-cell lymphoblastic tumors, and the phenotypic pattern must be that of an immature T cell. These tumors may have a leukemic presentation (T-ALL), or present as lymphoblastic lymphoma with tissue masses (T-LBL), although commonly blood, marrow, and tissue are all involved. To date, there is no convincing evidence that the leukemic and lymphomatous presentations are different biological entities, but extensive genomic investigation comparing T-LBL to T-ALL has not been performed. As noted, many treatment protocols use ≥25% bone marrow blasts as a cut-off for classification as T-ALL.

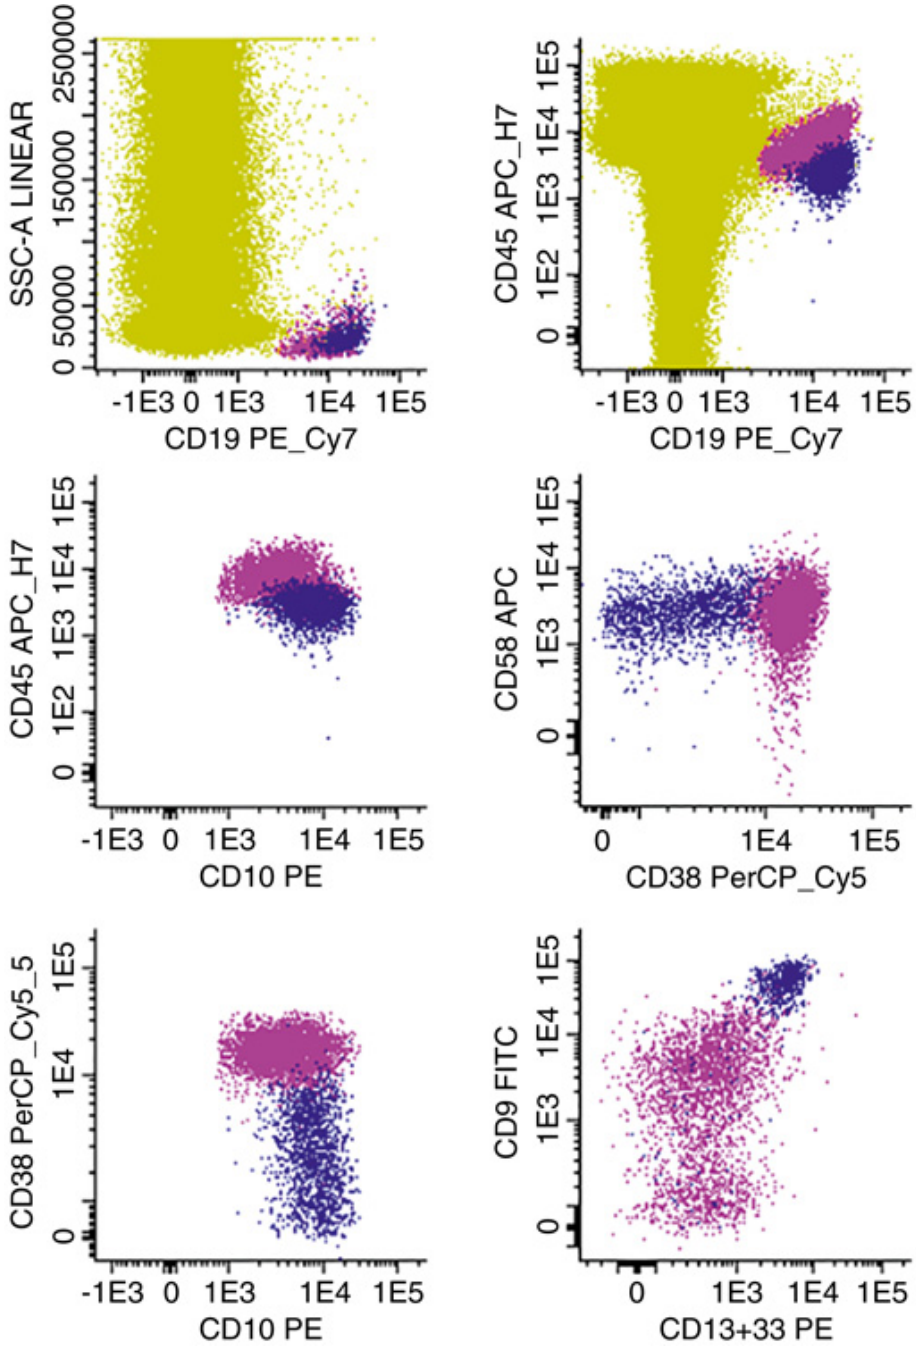

FIGURE 41-2 Minimal residual disease in B-ALL. Multiparametric flow cytometry showing the distinction between hematogones *(pink)* and residual B-ALL blasts *(blue)*. Blasts have slightly brighter CD19 and CD10 and slightly dimmer CD45 compared with hematogones but hematogones and blasts overlap in these

displays. However, blasts have much dimmer CD38 and brighter expression of CD9 and myeloid antigens CD13/33, allowing better separation from hematogones.

Synonyms and Related Terms

None.

Epidemiology

Perhaps because the thymus is the major site of normal T-cell development, the majority of T-LBLs are found in the mediastinum. T-lymphoblastic tumors account for only about 15% of childhood acute lymphoblastic leukemias, but nearly 90% of LBLs. LBLs are more common in late childhood and account for about one-third of all pediatric cases of non-Hodgkin lymphoma; they constitute only a small percentage of adult cases. Both leukemia and lymphomatous presentations show a male predominance.

Table 41-2

Differential Diagnosis of Acute Lymphoblastic Leukemia

Tumor	Distinguishing Features
Acute myeloid leukemia with minimal differentiation	Myeloid phenotype
Acute leukemias of ambiguous lineage	Co-expression of myeloid and lymphoid antigens or evidence of both myeloid and lymphoid differentiation
Lymphoid blast crisis of chronic myeloid leukemia (CML)	History of antecedent CML, Ph+
Chronic lymphocytic leukemia	Condensed nuclear chromatin, mature B-cell phenotype
Prolymphocytic leukemia	Lower nuclear-to-cytoplasmic ratio, prominent nucleolus, mature B-cell phenotype
Blastic variant of mantle cell lymphoma	Mature B-cell phenotype, t(11;14), cyclin D1 expression
Large B-cell lymphoma	Larger cells; mature B-cell phenotype
Burkitt lymphoma/leukemia	More prominent nucleoli; prominent basophilic

Tumor	Distinguishing Features
	cytoplasm; mature B-cell phenotype, t(8;14)
Small, round, blue cell tumors (including Ewing's sarcoma, neuroblastoma, embryonal rhabdomyosarcoma, medulloblastoma)	Cohesive growth, absence of lymphoid markers
Reactive proliferations of normal precursor B cells (hematogones)	Indistinct or absent nucleoli, normal continuum of B-cell antigen acquisition during differentiation

Table 41-3

Differential Diagnosis of Lymphoblastic Lymphoma

Tumor	Distinguishing Features
Myeloid sarcoma	More distinct cytoplasm, eosinophilic myelocytes, myeloid phenotype
Lymphocytic thymoma	Presence of abnormal cytokeratin^{+} thymic epithelial cells
Chronic lymphocytic leukemia/small lymphocytic lymphoma	Condensed nuclear chromatin, mature B-cell phenotype Smudge cells can be present in both acute lymphoblastic leukemia and chronic lymphocytic leukemia
Blastic variant of mantle cell lymphoma	Mature B-cell phenotype, t(11;14), cyclin D1 and/or Sox11 expression
Large B-cell lymphoma	Large cells, more prominent nucleoli, mature B-cell phenotype/absence of CD34 expression
Burkitt lymphoma	More prominent nucleoli, distinct cytoplasmic rim, mature B-cell phenotype, t(8;14)

Tumor	Distinguishing Features
Small, round, blue cell tumors (including Ewing's sarcoma, neuroblastoma, embryonal rhabdomyosarcoma, medulloblastoma)	May show cohesive growth, absence of lymphoid markers
Ectopic thymus	Indistinct or absent nucleoli, normal continuum of T-cell antigen acquisition during differentiation, normal epithelium
Indolent T-lymphoblastic proliferation	Extrathymic involvement, preserved architecture with interfollicular expansion, T-cell receptor gene rearrangement studies show polyclonality

Etiology

Although specific genetic disturbances are involved in T-lymphoblastic lesions, the underlying etiologic factors are unknown. Patients with ataxia telangiectasia have an increased risk of developing T-ALL, but only rarely develop B-ALL.[116]

Clinical Features

Patients with T-ALL typically present with high peripheral white blood cell counts (>50,000/μL), organomegaly, and peripheral lymphadenopathy. Children with T-ALL are typically older than those with B-ALL. The presence of a mediastinal mass is highly associated with a T-cell phenotype in ALL. Like patients with B-ALL, those with T-ALL may present with anemia,

thrombocytopenia, organomegaly, and bone pain; however, leukopenia is less common in T-ALL than in B-ALL.

Patients with T-LBL also have high tumor burdens, evidenced by advanced stage or bulky disease. In patients with mediastinal involvement, the mass is often quite large, leading to compromise of regional anatomic structures. This may manifest with clinical symptoms such as dyspnea caused by airway obstruction, dysphagia caused by esophageal compromise, or superior vena cava syndrome. Pulmonary and cardiac function may also be compromised by the presence of pleural or pericardial effusions.

Morphology

Like precursor B-cell lesions, leukemic and lymphomatous presentations of T-ALL are morphologically indistinguishable. Moreover, differentiating T-ALL from B-ALL by morphology alone is impossible. Cytologically, lymphoblasts range from small, round blasts with a high nuclear-to-cytoplasmic ratio, relatively condensed chromatin, and inconspicuous nucleoli to larger cells with increased amounts of blue-gray to blue cytoplasm, irregular nuclei with dispersed chromatin, and variable numbers of distinct nucleoli (**Fig. 41-3**). Cytoplasmic vacuoles are occasionally seen. Typically, T-cell lymphoblasts tend to have more cytologic heterogeneity and more nuclear convolutions than B lymphoblasts; however, no phenotypic, molecular, or clinical differences have been correlated with convoluted nuclear morphology. Histologically, T-LBL is a diffuse infiltrative process that occasionally involves lymph nodes in an interfollicular pattern but more commonly diffusely replaces the nodal architecture (**Fig. 41-4**). Frequently, the tumor grows in a single-file pattern and can extend through the capsule, infiltrating the perinodal fat. T-cell LBL tends to be a proliferative process with numerous mitotic figures. Rapid cell turnover can give rise to a starry-sky appearance as a result of the presence of tingible body macrophages, but this pattern rarely predominates to the extent seen in Burkitt lymphoma.

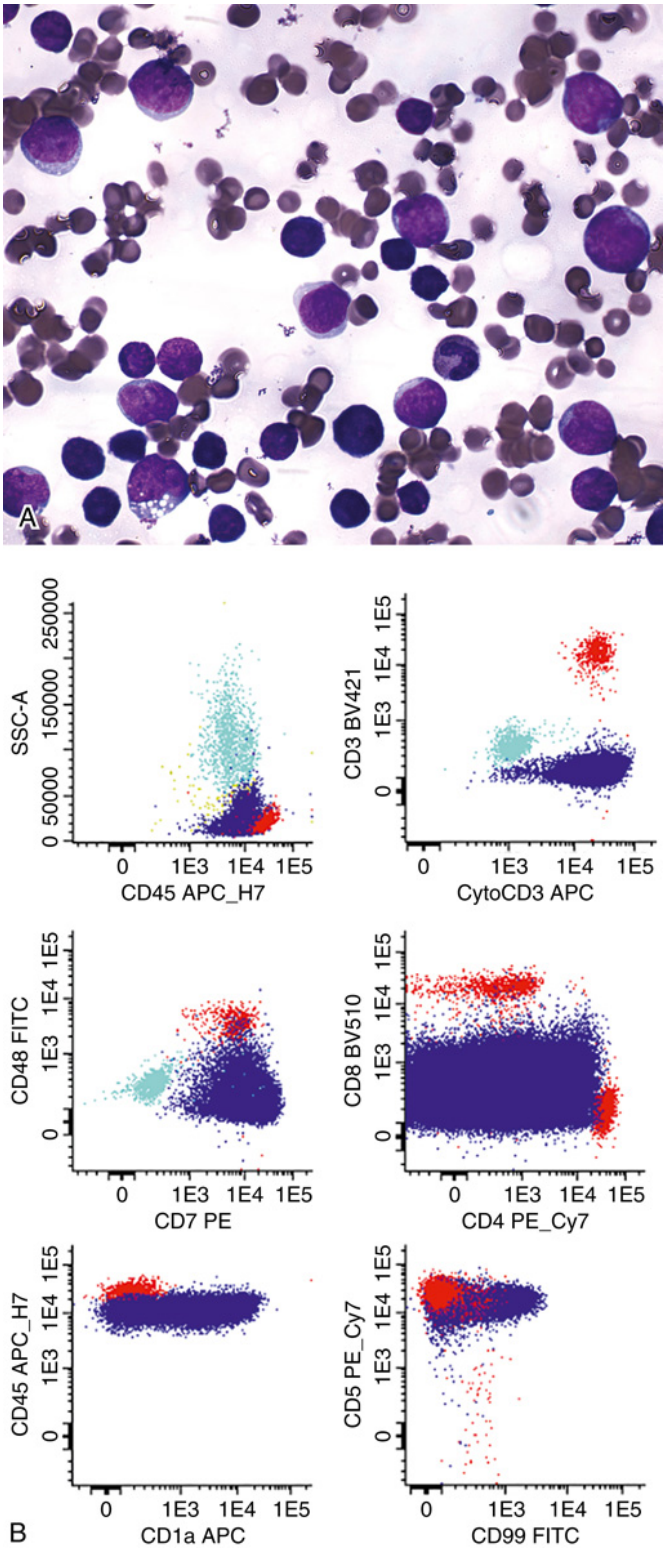

FIGURE 41-3 T-cell acute lymphoblastic leukemia.A, Bone marrow aspirate shows a predominant population of heterogeneous blasts with a

range of sizes. **B,** Multiparametric flow cytometry shows a population of abnormal T-cell blasts with slightly dim CD45 expressing cytoplasmic but not surface CD3, CD5, variable CD4 with limited CD8, partial CD1a, and CD99 with loss of CD48. Color convention as in Figure 42-1.

Immunophenotype

Precursor T-cell malignancies can express markers associated with T-cell differentiation and maturation in almost any combination (Fig. **41-3B** and **41-4**), although an understanding of phenotypic changes associated with normal T-cell maturation is helpful in understanding malignant phenotypes. Normal common lymphoid progenitors express TdT, CD34, and HLA-DR. Other early markers in T-cell differentiation include CD7, which can also be expressed on some myeloid precursors,[117] and CD2, which is also on dendritic cell precursors[118]; however, expression of cytoplasmic CD3 is generally considered the first definitive marker of T-cell lineage commitment. Early T-cell precursors first enter the thymus at the corticomedullary junction and proceed to the outer cortex, acquiring CD5 and CD1a and losing HLA-DR. These are the so-called "double-negative" thymocytes, which lack expression of CD4 and CD8. At this stage, the T-cell receptor (TCR) chains remain in a germline configuration. TCR gene rearrangement then occurs, with the sequential rearrangement of the δ, γ, β, and finally α chains. This allows the development of a functional TCR to permit thymic education through both positive and negative selection. The CD4, CD8 double-positive common thymocyte represents the major thymic population. The double-positive thymocytes that successfully engage major histocompatibility complex (MHC)-I are destined to be CD8-positive T cells, and those that engage MHC-II will become CD4-positive T cells. TdT continues to be expressed throughout cortical thymic development and is lost as the thymocytes enter the medullary phase of maturation.

Because precursor T-cell tumors resemble their normal thymic counterparts, knowledge of the normal patterns of antigen expression that highlight the uniqueness of thymocytes can be helpful in the recognition of T-cell ALL. For example, expression of TdT and CD1a on T cells outside the thymus does not normally occur; when seen, this typically indicates an abnormal population, although rare TdT-positive extrathymic cortical thymocytes can normally be seen in the tonsils and cervical lymph nodes. Most T-LBLs have a phenotype resembling a late cortical thymic phenotype, with expression of cytoplasmic CD3, TdT, and both CD4 and CD8. An important point is that virtually all precursor T-cell tumors have aberrant patterns of antigen expression that distinguish them from normal thymocytes. These changes include loss of pan–T-cell markers and aberrant co-expression of B-cell–associated antigens (CD24, CD9, CD21) or myeloid antigens (CD13, CD33), but as with B-ALL, the most common abnormalities represent deviation from the normal pattern of antigen expression with maturation.

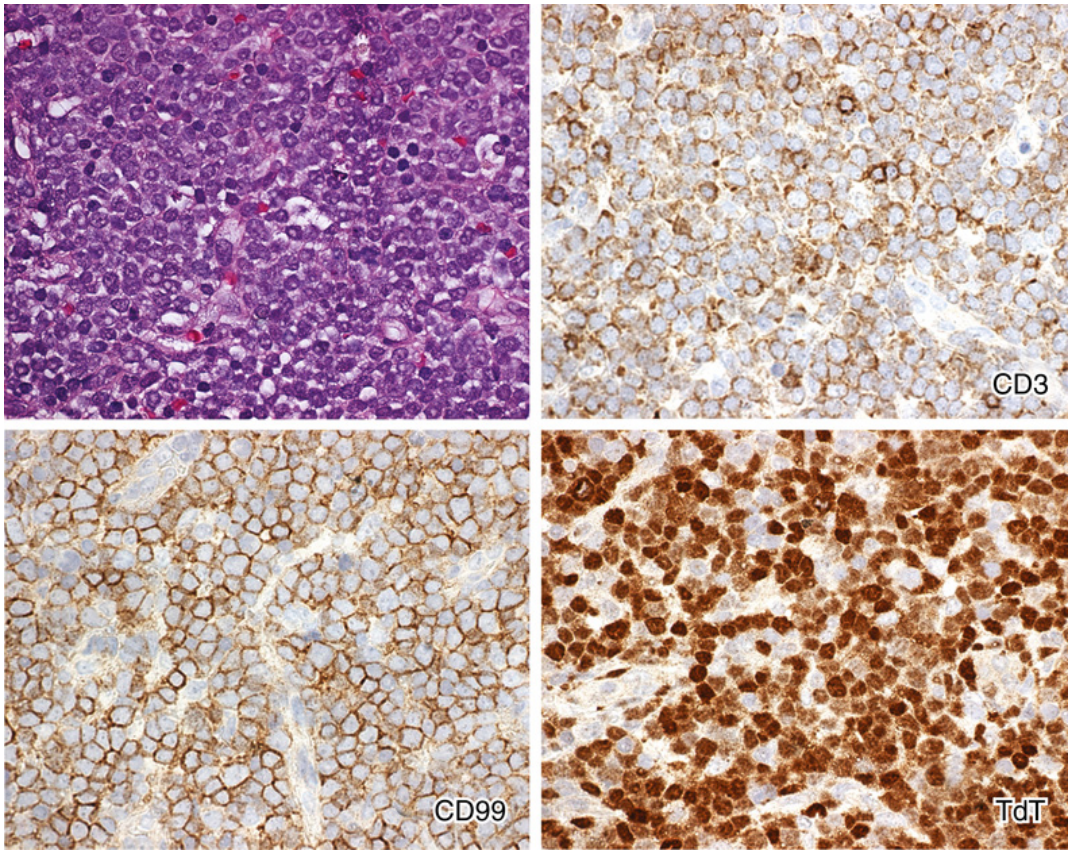

FIGURE 41-4 T-cell lymphoblastic lymphoma.Mediastinal mass shows malignant lymphoblasts with dispersed chromatin. The tumor expresses CD3, CD99, and terminal deoxynucleotidyl transferase (TdT), as indicated.

In some cases, T-cell ALL has a more primitive immunophenotype than T-cell LBL, perhaps reflecting either an earlier thymocyte precursor or even an earlier bone marrow progenitor. These cases of so-called “early T-cell precursor” (ETP) ALL represent a formal category of T-ALL in both the ICC and the proposed WHO 5th edition. ETP ALL is defined by its distinctive immunophenotype: CD1a negative, CD8 negative, and limited CD5 expression (<75% of blasts), with stem cell or myeloid antigen expression, including CD34, HLADR, CD13, CD33, CD117, CD15 and/or CD65.[119] Most of these cases also express TdT.[120] ETP ALL invariably expresses CD7, which appears to be the most sensitive antigen for T-cell ALL; however, CD7 is also

frequently expressed in AML, including some cases of myeloperoxidase-negative AML.[121] Though ETP ALL frequently expresses myeloid antigens, by definition it does not express MPO. Clinical studies of ALL initially suggested that patients with ETP ALL have a particularly poor prognosis[119]; however, more recent studies using intensive therapy showed a slower initial response to therapy in ETP ALL compared with other T-ALLs, but no significant difference in survival.[122]

A subset of T-ALL that otherwise meets criteria for ETP ALL but that shows expression of CD5 on ≥75% blasts is often referred to as "near-ETP ALL".[123] Despite the immunophenotypic similarity to ETP ALL, near-ETP ALL has different genetic lesions than ETP ALL, with enrichment for *TLX3*-rearrangements. Near-ETP ALL also shows minor differences from ETP ALL in clinical presentation and response to therapy and is not included in formal classification systems.

In some cases, definitive distinction between AML and T-ALL may also be difficult. TdT is expressed in over 90% of T-ALL, and although it is present in up to 20% of AML cases, bright expression of TdT favors T-ALL.[124] HLA-DR may be helpful because it is expressed in virtually all CD7-positive AMLs but in only a small portion of T-cell ALLs. T-cell antigens such as CD1a, surface CD3, and CD8 show higher specificity for T-ALL, but they are often not expressed. Of all the markers, cytoplasmic CD3 appears to be the most reliable marker for establishing T-cell lineage and is expressed by virtually all precursor T-cell neoplasms. Cytoplasmic CD3 is brightly positive in most cases of T-ALL but may be dim, in which case distinction from AML may be more difficult.

Genetics and Molecular Findings

As mentioned, during normal T-cell development, there is an ordered rearrangement of TCR chain loci, starting with the δ chain, followed by γ and β, and finally, if γ and δ fail to generate a competent rearrangement, T-cell receptor α (TRA). T-ALLs often show patterns of TCR gene rearrangement that reflect this. As such, the most primitive T-ALL may have no rearranged

TCR genes or only show TCR γ (TRG) rearrangement. TRA often remains in a germline configuration, except for tumors with the most mature phenotypes. Although TCR rearrangements are a vital step in T-cell development, there is significant lineage infidelity at the molecular level, and TCR rearrangements are also frequently observed in B-ALL. The rearrangement of IGH loci in precursor T-cell tumors is less frequent, and IGL locus rearrangement is almost never observed in precursor T-cell neoplasms.

In addition to the demonstration of TCR gene rearrangements, a number of nonrandom chromosomal translocations have been consistently observed in precursor T-ALL. Unlike precursor B-cell lesions, which rarely involve the immunoglobulin loci, these translocations frequently involve the TCR loci on chromosomes 7 and 14.[125] Most of the rearrangements involve transcription factors, suggesting disruption or inappropriate regulation of these factors contribute to leukemogenesis. In fact, it has long been recognized that T-ALL could be divided into families based on dysregulation of different transcription factors.[126] More recently, GEX studies similar to those performed in B-ALL have shown distinct clusters of T-ALL cases. Each cluster shares activation of common transcription factors. However, in contrast to B-ALL, where many cases in clusters share a common translocation, the T-ALL entities within each cluster may have various alterations (e.g., TCR rearrangements, chimeric fusion oncoproteins, and enhancer mutations) that deregulate different drivers; thus, comprehensive genomic analysis may be required to classify all cases. Moreover, the identification of a specific translocation in T-ALL may not be sufficient to define an entity, because many different genetic lesions may result in the downstream activation of the same pathways with similar GEX profiles. As a result of the complexity of the mechanisms associated with T-cell leukemogenesis, all members of a class can only be identified by GEX profiling or comprehensive genomic analysis. These methods are not routinely available in a clinical setting, and there is still no formal use of this transcription-based classification in ALL treatment protocols; therefore, entities defined in this manner are considered provisional in the ICC and are

not part of the provisional WHO 5th edition (**Box 41-2**). However, there is evidence of clinical differences among these entities, some of which are summarized in **Table 41-4**.

An interesting observation from GEX studies of cases of ETP ALL was that a subset, comprising about 30% of cases, formed a distinct cluster separate from all other T-ALL cases. Further investigation into these cases revealed that this cluster had in common activation of the T cell transcription factor gene *BCL11B*. Approximately 80% of cases of ETP ALL with *BCL11B* alterations are associated with interchromosomal rearrangements that result in upregulation of BCL11B protein, and the remaining cases overexpress BCL11B via focal amplifications that generate a neoenhancer distal to the gene; for these reasons, this group has been termed "*BCL11B* activated" (*BCL11B*-a), rather than "*BCL11B* rearranged." Because *BCL11B*-a cases are biologically so different from other cases of ETP ALL, it is considered a new entity in the ICC (**Table 41-4**). These cases can be recognized by immunohistochemistry for BCL11B.[127] It is, however, important to use immunostaining for BCL11B to subclassify only cases of immunophenotypically proven ETP ALL, because BCL11B can also be upregulated in other types of T-ALL such as *TLX3*-dysregulated T-ALL.

Other Genetic Lesions in T-ALL

As is the case with B-ALL and AML, cases of T-ALL have cooperating mutations that are seen across many different entities. Among the most common, *NOTCH1* gene mutations have been implicated in the pathogenesis of a significant subset of T-ALL.[128,129] Although only rare cases with a (7;9) translocation involving *NOTCH1* have been identified, point mutations, insertions, and deletions in the *NOTCH1* gene, all leading to an increase in signaling, have been found in more than half of T-ALL cases, including those in all the molecular subgroups previously noted.[129] This suggests that these mutations play a central role in pathogenesis. Of interest, the increased *NOTCH1* signaling associated with these mutations is dependent on the downstream activity of γ secretase,[128] suggesting that γ secretase inhibitors

might play a role in the treatment of T-cell ALL. Also common in T-ALL are deletions in *CDKN2A/B,* seen in about 70% of cases and considered fundamental to T-cell leukemogenesis. Other common mutations affect the JAK-STAT or RAS pathways.[129]

Table 41-4

Characteristics of Novel T-ALL Entities in the ICC

Subtype	Frequency and Clinical Features	Maturational Stage
***BCL11B*-activated**	~30% of ETP ALL, prognosis possibly better than other ETP ALL	ETP: CD7+, CD5− (<75%), CD8−,CD1a− with myeloid or stem cell antigens
***TAL1/2*-dysregulated**	30%–40% of T-ALL (TAL2 rare) poor prognosis	Late cortical-medullary thymocyte, often CD3+
***TLX1*-rearranged**	5%–10% children ~30% adults very good prognosis	Cortical thymocyte
***TLX3*-rearranged**	20%–25% children, <5% adult, very good prognosis	Some near-ETP/cortical thymocyte
***HOXA*-dysregulated**	15%–25% variable prognosis	Immature, many ETP
***LMO1/2*-dysregulated**	5%–10% LMO2>LMO1 and has worse prognosis	Immature, some ETP
***NKX2*-rearranged**	<5% children	Late cortical thymocyte
***SPI1*-rearranged**	<5% children, very poor prognosis	Early cortical thymocyte

Subtype	Frequency and Clinical Features	Maturational Stage
***bHLH*, other**	<2%	Immature

ETP ALL, Early T-cell precursor acute lymphoblastic leukemia; *T-ALL,* T-lymphoblastic leukemia/lymphoma.

ETP T-ALL, however, characteristically lacks *NOTCH1* mutations, and instead is frequently associated with mutations such as *FLT3* (both ITD and D835), *DNMT3A, WT1,* and *RUNX1* that are more typically associated with myeloid disease. In addition, ETP T-ALL has a relatively low frequency of clonal TCR rearrangements[130] and a global transcriptional profile similar to that of normal hematopoietic and myeloid leukemia stem cells,[131] suggesting these neoplasms arise from early hematopoietic progenitors or stem cells. Interestingly, the *BCL11B* activation seen in the ETP ALL subset can also be seen in cases of AML, undifferentiated leukemia, and T/myeloid MPAL, and GEX studies show that all such cases co-cluster.[132,133] Whether the myeloid-related and stem cell related genetic features of ETP ALL are enriched in the *BCL11B*-a subset is as yet unknown.

Normal Counterpart

The normal counterpart of T-cell ALL/LBL is thought to be the precursor T cells that arise from bone marrow–derived hematopoietic stem cells that migrate to the thymus, where they develop. As noted, these precursor cells possess unique antigen-expression patterns that clearly distinguish them from more mature extrathymic T cells.

Clinical Course

Children with T-ALL generally have a more aggressive clinical course than those with B-ALL,[134,135] which is due, in part, to the characteristic presence of higher-risk clinical features. T-ALL tends to occur in older children, and patients have higher white blood cell counts. These patients also have a higher incidence of CNS involvement. Adults with T-ALL are typically treated

with intensive therapy. These patients may actually fare better than those with B-ALL, likely reflecting the relatively high incidence of B-ALL with *BCR*::*ABL1* and *BCR*::*ABL1*-like B-ALL in adults. Patients with T-LBL with even minimal bone marrow disease at diagnosis have a poorer prognosis than those without it.[136] The majority of patients with T-LBL have advanced disease, evidence of B symptoms, and high lactate dehydrogenase levels. In contrast to leukemic presentations, there is typically preservation of peripheral blood counts, presumably owing to the lack of bone marrow replacement. Bone marrow or testicular involvement by LBL is strongly correlated with CNS disease. Historically, LBL has been an aggressive disease associated with poor survival in response to standard lymphoma therapy.

As a result of the similarities between T-cell ALL and LBL, most LBLs are treated with ALL-like therapy. On the adoption of these ALL-like regimens, dramatic improvements in outcome were seen,[137] particularly for low-stage LBL. Studies in adult patients with T-cell LBL indicated that they too can benefit from ALL-type regimens.[138] Another important therapeutic strategy is CNS prophylaxis, given the high rate of CNS relapse in patients who do not receive it. Because local recurrence is also a major indication of treatment failure, inclusion of mediastinal radiotherapy may play a role in preventing relapse, particularly in adult patients. MRD in T-ALL is also prognostically important; however, available data suggest that T-ALL responds more slowly than B-ALL, so MRD measured at later timepoints is more prognostically relevant than MRD measured at the end of induction therapy.[139]

Although intensified ALL-type therapy has improved outcomes in T-cell LBL, knowledge of biological features that predict remission or survival is still limited, and risk stratification largely depends on disease stage and initial response to therapy.

Differential Diagnosis

The distinction of T-ALL or T-LBL from other neoplasms (Tables **41-2** and **41-3**) typically rests on immunophenotypic analysis. Recognition that precursor T-cell tumors have an abnormal immunophenotype can help

distinguish these neoplasms from thymic tissue if sent for flow-cytometric analysis, because normal thymocytes and those of thymoma will typically show a normal pattern of T-cell maturation, in contrast to the aberrancies seen in neoplasia.[140] T-LBL occurring in the mediastinum may sometimes be confused with thymomas histologically, especially if a thymic T-cell phenotype demonstrated by immunohistochemistry is misinterpreted. Cytokeratin staining is helpful in avoiding this pitfall, provided attention is paid to the different pattern of cytokeratin expression in thymoma versus residual thymus.

It is also important to distinguish T-ALL from benign entities. In the case of T-LBL, one important condition to consider is an "indolent T-lymphoblastic proliferation."[141,142] This entity often involves head and neck nodes and is remarkable for paracortical expansion by phenotypically normal T-cell precursors without architectural effacement of the node. It can also be seen in nodes involved by carcinoma or lymphoma. As this rare entity requires no or only local therapy, its recognition is critically important.

Conclusion

Precursor lymphoid neoplasms are aggressive tumors that require immediate diagnosis and treatment. However, with appropriate intensive therapy, these malignancies may be curable, particularly in the pediatric population. Greater understanding of the biology of lymphoblastic tumors and the enhanced specificity in new classification systems will allow for improved risk stratification and the development of targeted therapeutic agents.

Pearls and Pitfalls

Diagnosis of Acute Lymphoblastic Leukemia (ALL)

Pearls

- Precursor B-cell neoplasms generally present as leukemias, and precursor T-cell neoplasms generally present as lymphomas; if leukemic, the latter are associated with significant tissue involvement. Mediastinal masses in patients with ALL are seen almost exclusively with precursor T-cell neoplasms.
- Precursor lymphoid tumors recapitulate certain aspects of normal precursor lymphoid maturation. However, because of the reproducible nature of antigen acquisition in normal precursors, virtually all neoplastic populations can be reliably distinguished from normal precursors by multiparametric flow cytometry.
- For B-cell ALL, the presence of hyperdiploidy or *ETV6-RUNX1* fusion confers a favorable prognosis in childhood, whereas *BCR*::*ABL1* fusion or *KMT2A* rearrangement confers a poor prognosis. *BCR*::*ABL1*-like ALL is also a poor prognosis lesion.
- Bone marrow and testicular involvement by lymphoblastic lymphoma is associated with CNS involvement.

Pitfalls

- Precursor lymphoid tumors may lack common leukocyte antigen (CD45) and express CD99; as such, this profile does not distinguish them from Ewing's sarcoma. Inclusion of other lymphoid markers and TdT may be helpful in distinguishing between these alternatives.
- CD79a, commonly used as a B-cell marker, may be occasionally expressed on T-cell tumors, including precursor T-cell neoplasms.
- Expression of myeloid antigens such as CD13, CD33, and CD15 occurs commonly in B-cell ALL and does not imply that the tumor is biphenotypic (see **Chapter 43**).
- In the absence of morphology suggestive of Burkitt lymphoma/leukemia or of an *MYC* translocation, expression of clonal surface IGL does not exclude a diagnosis of B-cell ALL.

- The presence of CD19-positive CD10-positive cells in the bone marrow, even in significant numbers, does not necessarily establish a diagnosis of B-cell ALL because these cells must be distinguished from normal B-cell precursors (hematogones).
- Dim MPO expression can be detected by flow cytometry or immunohistochemistry in B-ALL and should not be the sole criterion for a diagnosis of B/myeloid MPAL.
- Patients with ALL with packed marrows may be aleukemic but circulate occasional myeloblasts pushed out from the marrow; thus, a diagnosis of AML should not be made without marrow examination if only a few myeloblasts are identified in peripheral blood by flow cytometry.

DIFFERENTIAL DIAGNOSIS

Definitions

Acute leukemias of ambiguous lineage (ALAL) are those leukemias that either fail to show evidence of myeloid, B-lymphoid, or T-lymphoid lineage commitment or show evidence of commitment to more than one lineage.[1-4] These leukemias include acute undifferentiated leukemia (AUL) and mixed-phenotype acute leukemia (MPAL). MPAL includes both biphenotypic leukemia (a leukemia with more than one lineage-defining marker on a single blast population) and bilineal leukemia (a leukemia composed of two or more single-lineage leukemia populations). AUL is a rare type of acute leukemia that shows no evidence of differentiation along any lineage and is included under ALAL in classifications of acute leukemias.

Synonyms and Related Terms

Initial classification systems of ALAL used a scoring system whereby certain lineage markers were assigned points, with the diagnosis of biphenotypic acute leukemia (BAL) dependent on a final score reached.[5] The first scoring system was described by Catovsky et al. The European Group for the Immunologic Characterization of Leukemias (EGIL) further modified the Catovsky system, primarily by increasing the weight of certain markers and adding and subtracting others[6,7] (**Table 42-1**); subsequently, the World Health Organization (WHO) 3rd edition of the Classification of Tumours of Haematopoietic and Lymphoid Tissues (2001) included this system.[8] The WHO 4th edition eliminated a scoring system and sought to simplify the diagnosis by reducing the specific markers necessary to ascribe a lineage to biphenotypic leukemias and combined

biphenotypic leukemias and bilineal leukemias within the MPAL category; the revised WHO 4th edition classification kept this approach.[9] Both the proposed WHO 5th edition and the International Consensus Classification (ICC) of acute leukemias continued using lineage-specific markers outlined in the WHO 4th edition and included more genetically defined subtypes[10,10a,11] (**Tables 42-2** and **42-3**). Based on the markers expressed on the blast cells, BAL/MPAL can also be further divided into B/myeloid, T/myeloid, B/T-cell, and B/T/myeloid subtypes.

Epidemiology

The incidence of MPAL depends on the classification used. Historically, BAL accounted for up to 5% of acute leukemias.[12] The updated WHO classifications led to a decreased number of MPAL cases, and in the two largest case series using the WHO criteria, MPAL cases accounted for between 0.5% and 2.4% of all leukemias.[13] In a study of 7627 pediatric and adult patients with acute leukemia, 2.8% had bilineal acute leukemia using the EGIL classification, and 1.6% had MPAL using the 4th edition of the WHO classification.[14] The incidence of MPAL has a bimodal age distribution with peaks observed at 19 and 60years of age.[15] Because of its rarity, little is known about AUL. Using the SEER database, the age-adjusted AUL incidence rate is reported to be 1.34 per million person-years[16]; however, this appears to have decreased over time, likely the result of better diagnostic tools assigning patients either to the myeloid or lymphoid lineage.

International Consensus Classification (ICC) of Acute Leukemia of Ambiguous Lineage

MPAL with defining genetic alterations
MPAL with *BCR*::*ABL1*
MPAL with t(v;11q23.3), *KMT2A* rearrangement
MPAL with *ZNF384* rearrangement
MPAL with *BCL11B* activation
MPAL with defining immunophenotypic changes
B/myeloid MPAL
T/myeloid MPAL

B/T/myeloid MPAL

B/T MPAL

Acute undifferentiated leukemia (AUL)

Acute leukemias of ambiguous lineage, not otherwise specified (ALAL, NOS)

Clinical Features

Patients with MPAL generally present with clinical findings that reflect pancytopenia, such as fatigue, weakness, infections, and/or bleeding (e.g., epistaxis, gingival bleeding, ecchymoses). Other findings may relate to accumulation of leukemic cells in peripheral blood, bone marrow, or extramedullary sites (e.g., abdominal fullness from splenomegaly, bone pain). This clinical presentation does not distinguish MPAL from other forms of acute leukemia.

Diagnostic Criteria and Lineage Assignment

Blasts in MPAL are morphologically diverse and range from small to intermediate in size with variable cytoplasm, and in some cases, two separate blasts with distinctive size, morphology, and phenotype can

be identified (**Fig. 42-1**). Extensive immunophenotyping is essential for an accurate diagnosis of ALAL. Lineage assignment is best performed by flow cytometric immunophenotyping to correlate the patterns of antigen expression on one or more cell populations. When evaluating the flow cytometry data and particularly co-expression of markers, it is important to exclude doublets and address compensation (process of correcting for fluorescence spillover) and autofluorescence issues so that dim populations can be differentiated from negative populations. Immunohistochemical stains may be used to show expression of lineage-associated antigens such as MPO, CD3, and PAX5 (**Table 42-4**). The proposed WHO 5th edition stresses that the assignment of lineage by immunophenotyping is dependent on the strength of association between each antigen and the lineage being assessed. As a general principle, the closer the expression of an antigen is to either the intensity and/or pattern of expression seen on the most similar normal population, the more likely it reflects commitment to that lineage. Unlike the EGIL, the WHO does not clearly provide a threshold for the percentage of cells for lineage-specific antigens, but they recommend a level of expression exceeding 50% of that seen on normal mature T-cells and B-cells or neutrophils. In the most recently proposed WHO classification, the intensity of antigen expression is considered to be more lineage specific.

The diagnosis of ALAL requires the presence of ≥20% blasts in peripheral blood or marrow. In bilineal MPAL cases, each abnormal progenitor population must meet the immunophenotypic criteria for that lineage, but the numerical blast criterion only applies to aggregate. In cases with separate blast populations, each population

needs to be classified according to acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) criteria (**Fig. 42-1**). The ICC proposed that, in cases with small aberrant clones of divergent lineage (>5%), a diagnosis of MPAL could be rendered if clear immunophenotypic aberrancies are identified. Identification of such aberrancies is essential to differentiate a small bilineal blast population from normal myeloid or B-cell precursors. For cases with aberrant clones which represent less than 5% of all cells, a diagnosis should be based on the major leukemic population with a descriptive modifier.

AUL is rare and defined by the absence of both myeloid and lymphoid markers. Little is known about its incidence, survival, and optimal management.

In a multi-institutional study of AUL cases, a significant number of cases were reclassified as AML with myelodysplasia-related changes (AML-MRC) based on cytogenetic findings, and only a small number (24 cases) were qualified as AUL.[17] Of these, only six AUL cases showed no myeloid marker expression (CD117, CD13, or CD33), though 15 showed partial or full expression of one myeloid marker. Restricting the definition of AUL to cases with one or fewer myeloid marker expressions showed no difference in overall survival or relapse-free survival when comparing this group with AML with minimal differentiation. Compared with AML with minimal differentiation, AUL cases were characterized by significantly more frequent mutations in *PHF6,* and this difference was even more significant when reassigning AUL cases with partial expression of a second myeloid marker to the AML with minimal differentiation group.[17]

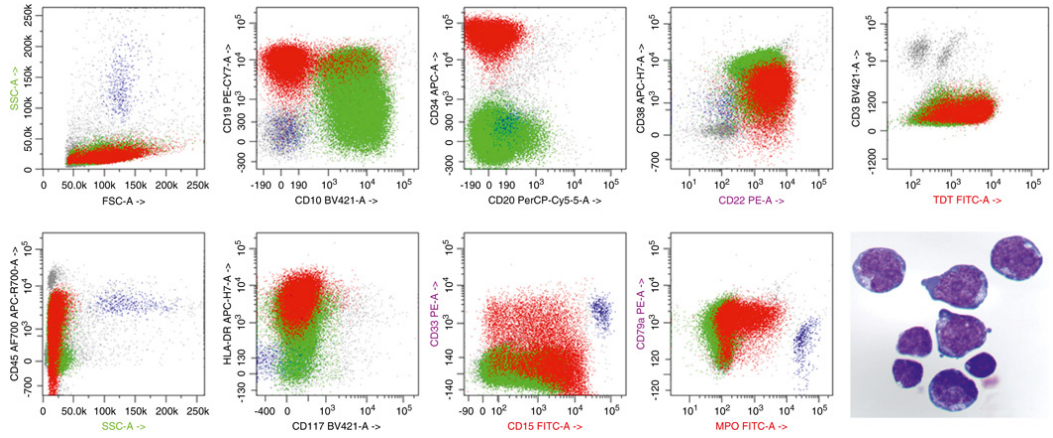

FIGURE 42-1 Flow plots of MPAL, B/myeloid with *EP300*::*ZNF384*. Flow cytometry plots illustrate a population of B-lymphoblasts *(green)* accounting for 70% and a B/myeloid population accounting for 24%. The aspirate smears show two separate populations of blasts *(inset)*.

Table 42-4

B Lineage

Assignment of B lineage requires strong CD19 expression on blasts in addition to strong expression of at least one other B-lineage marker (**Table 42-4**) or weak CD19 expression, requiring two additional markers. The most specific marker for B-lineage leukemias is CD19; however, it can be detected in a subset of AML, including t(8;21)(q22;q22.1) rearranged AML, which precludes its use as the sole lineage assignment marker.[18,19] The proposed WHO 5th edition recommends that a level of expression exceeding 50% of that seen on normal mature B cells should be seen on at least a portion of the

leukemic cells, though the ICC does not have this requirement. The additional B-lineage marker CD79a is expressed early in B cells and is retained through plasmacytic differentiation; however, its expression is not unique to acute leukemias of B lineage.[20] CD10 is similarly expressed early in B-cell development; however, it is detected in a subset of T-cell acute lymphoblastic leukemia (T-ALL), making it less sensitive and specific than CD19.[21] Cytoplasmic expression of CD22 is detected in most cases of B-cell acute lymphoblastic leukemia (B-ALL) and not identified in AML or T-ALL, but its expression in basophils and dendritic cells make it less specific for assigning B lineage.[22,23]

T Lineage

For T lineage, blasts must express CD3 on the surface or within the cytoplasm. The proposed WHO 5th edition recommends that a level of expression exceeding 50% of that seen on normal mature T cells should be seen on at least a portion of the leukemic cells, though the ICC does not have this requirement. The WHO also recommends using a bright fluorochrome such as phycoerythrin (PE), allophycocyanin (APC), or Brilliant Violet (BV) dyes to provide an increased dynamic range to aid in this determination. An example of a T/myeloid MPAL is shown in **Figure 42-2**. Other T-cell markers, including CD2, CD4, CD5, CD7, CD8, and TCR αβ, have been used in prior scoring systems; however, CD2 and CD7 are commonly found expressed on blasts for leukemias that otherwise are consistent with AML, and CD4 is expressed on early granulocytic, monocytic, and dendritic precursors.[22,23]

Myeloid Lineage

Myeloid lineage is assigned when blasts express myeloperoxidase (MPO), or at least two of the following monocytic markers: non-specific esterase, CD11c, CD14, CD64, or lysozyme. MPO has long been considered the most specific marker for myeloid-lineage leukemias.[24] MPO expression by immunohistochemistry, cytochemistry, or flow cytometry or monocytic differentiation is considered a requirement for assigning the myeloid lineage when considering a diagnosis of MPAL. Variable MPO expression with an intensity and pattern similar to that seen in early myeloid maturation is more strongly associated with myeloid lineage than uniform dim MPO expression. Although older studies suggest a cutoff of 3% for cytochemistry based on expert opinion (**Table 42-5**), no formally established cutoff guidelines exist for immunohistochemistry and flow cytometry.[25-30] The issue is further compounded by the availability of many MPO clones, known non-specific staining patterns, and lack of criteria for evaluating the stains, especially in cases that may contain a significant number of non-blast myeloid cells. To standardize flow cytometric interpretation of MPO based on internal positive and negative control populations, the proposed WHO 5th edition has clarified that the intensity of MPO expression on blasts must exceed 50% of the background mature neutrophils and both the WHO and ICC recommend a 10% cut off.[10,11]

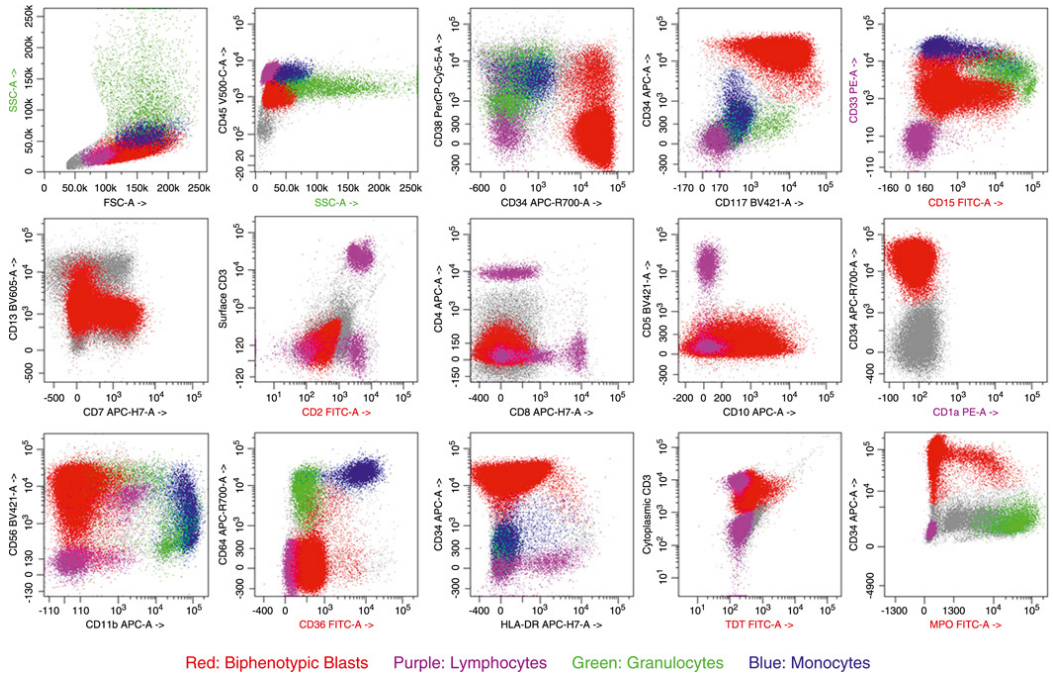

FIGURE 42-2 Flow cytometry plots of MPAL, T/myeloid case. Blast population in red shows expression of CD34 and CD117, variable expression of myeloid markers including CD33, CD13, MPO, and CD15, and T-cell markers including cytoplasmic CD3, CD56, CD7, and CD10.

Genetic and Molecular Findings

The majority (64%–87%) of MPALs have an abnormal karyotype.[31] The most common abnormalities are rearrangements of t(9;22) and t(v;11q23.3), and these now form specific subgroups of MPAL (WHO and ICC). MPALs with *KMT2A* rearrangement are more common in the pediatric group (infants) and account for about 10% of MPALs. MPAL with *BCR*::*ABL1* is more common in adults and accounts for about 20% of MPAL cases.[32] In addition to these two widely

recognized aberrancies, other cytogenetic abnormalities, particularly observed in the B/myeloid subtype, include del[1](p32), trisomy 4, del(6q), and 12p11.2 abnormalities and near-tetraploidy.

Table 42-5

Myeloperoxidase Antibodies Used and the Cutoff Recommended in Various Studies

Study	Antibody	Threshold Recommendations
Van den Ancker et al., 2013	Flow cytometry (clone used not reported)	>10%
Arber et al., 2001	IHC 1:1000 dilution, Dako, Carpinteria, CA), polyclonal and monoclonal MPO antibody (clone MPO-7;1:100 dilution; Dako)	≥5%
Ahuja et al., 2018	IHC: anti-human MPO (Thermo Scientific, United Kingdom)	3% for IHC 10% for cytochemistry
Oberley et al., 2017	Flow cytometry: MPO (clone 8E6; Life Tech, Waltham, MA) IHC (clone 59A5; Leica Biosystems,	>20% for flow cytometry 3% cytochemistry

Study	Antibody	Threshold Recommendations
	Newcastle, United Kingdom) plus cytochemistry	
Guy et al., 2013	Flow cytometry: monoclonal antibody (Dako or Immunotech), FITC	>13% (if using isotype control) >28% (if using internal control: lymphocytes)
Matutes et al., 2011	Flow cytometry: monoclonal MPO (clone used not reported)	>10%

FITC, Fluorescein isothiocyanate; *IHC,* immunohistochemistry.

Studies have performed genomic analyses of MPAL cases and have found that gene mutations are a mixture of those commonly seen in both AML and ALL. In 2012, Yan et al. reported deletions of the ALL-associated gene *IKZF1* and mutations of the AML-associated epigenetic modifiers *TET2, EZH2,* and *ASXL1* in B/myeloid leukemias.[33] In 2016, Eckstein and colleagues performed whole exome sequencing on 23 cases of MPAL; they found similar mutations and identified AML-associated *DNMT3A* mutations, *WT1* mutations, and frequent *NOTCH* mutations (32%) in cases with a T-lineage component, suggesting genetic overlap with unilineage T-ALL.[34] In a series of 31 cases, Takahashi et al. reported genomic anomalies and methylation patterns in a comparison of T/myeloid

and B/myeloid MPALS with AML, T-ALL, and B-ALL.[31] They found both AML-type and ALL-type mutations in MPAL, and more mutations and broader methylation profiles were present in T/myeloid MPALs than in B/myeloid MPALs. B/myeloid MPALs typically presented with *RUNX1* mutations, and T/myeloid MPALs were enriched in *NOTCH1* mutations. It is interesting to note that analysis of the methylome showed T/myeloid MPALs preferentially segregated with T-ALL and B/myeloid MPALs preferentially segregated with AML.[31] T/myeloid MPAL appears to consist of a more heterogeneous group of driver mutations, with fusions that overlap with T-ALL such as *ZEB2*::*BCL11B* and *NUP214*::*ABL1* and fusions with *ETV6* involving multiple different partners. In a study of 8 pediatric and 18 adult patients, Xiao and colleagues identified recurrent and largely mutually exclusive alterations in *PHF6, DNMT3A,* and *WT1* in MPAL with a T-lineage immunophenotype.[35] A series of B/T MPALs has identified recurrent acquired aberrations, including mutations in the putative transcriptional regulator *PHF6* and the JAK-STAT and Ras signaling pathways.[36]

Whole exome and genome sequencing in a cohort of 115 pediatric MPAL/ALAL cases identified *WT1, FLT3, RUNX1,* and *PHF6* mutations among the most recurrent alterations in pediatric T/myeloid MPAL.[37] Fusion genes involving the *ZNF384* transcription factor gene were identified in nearly 50% of cases and more prominent in B/myeloid MPAL. *ZNF384* fusions are also common in B-ALL,[17,18] which had an overlapping gene expression profile with *ZNF384*-rearranged B/myeloid MPAL, supporting the notion that genomic alteration, rather than immunophenotype, more accurately classifies certain subtypes of leukemia. An example of a

ZNF384-rearranged case is shown in **Figure 42-1**. These fusions were not identified in adult B/myeloid cases, confirming that subsets of pediatric and adult MPAL have distinct genetic origins. ALAL with rearrangements leading to deregulation of *BCL11B* (BCL11B-activated) accounts for 10% to 15% of MPAL and is further enriched in patients with T/myeloid MPAL cases, representing up to one-third of this population.[38-40] Unlike the *BCL11B* alterations described for T-ALL (amino acid substitutions and deletions and rearrangements of the *BCL11B* enhancer to *TLX3*), the 14q32 structural variants identified in ambiguous lineage leukemias usually leave the *BCL11B* coding region intact. These alterations involve juxtaposition of super-enhancers active in hematopoietic stem cells to *BCL11B,* or in 20% of cases, amplification of a 2kb region distal to *BCL11B* resulting in generation of a neo-enhancer that deregulates *BCL11B* expression.

Based on these findings, the proposed WHO 5th edition and ICC systems recognize two new entities with defined genetic alterations, MPAL with *ZNF384* rearrangements and MPAL with *BCL11B* activation.[10,11] Though *ZNF384* rearrangements have been identified in B-ALL, Alexander et al. characterized them in the pediatric setting at a rate of 48% of B/myeloid MPAL.[37] Gene expression profiling suggests *ZNF384*-rearranged MPAL more closely resembles B-ALL than AML, with a maturation profile that is more mature than in most B/myeloid MPAL cases but less mature than in most B-ALL cases. *BCL11B* cases present with absence of CD5 and expression of cCD3 or MPO, resulting in variable classification, and are driven by aberrant allele-specific deregulation of BCL11B, a master transcription factor responsible for thymic T-lineage commitment and specification. Mechanistically, this deregulation was driven by

chromosomal rearrangements that juxtapose *BCL11B* to super-enhancers active in hematopoietic progenitors or focal amplifications that generate a super-enhancer from a noncoding element distal to *BCL11B*.[40] Moreover, emerging work is showing that the biology of immature leukemias is explained by diverse genomic alterations converging on a conserved set of stem cell genes, showing phenotypic ambiguity: early T-cell precursor (ETP), MPAL, or neither; this further suggests that genetic alterations rather than phenotypic expression may in the future be a better way of classifying these leukemias.[40]

Clinical Course

It has been widely recognized that the clinical outcome of ALAL is markedly adverse, and the overall survival (OS) ranges from 9 months to 3.5 years according to published data.[13,41,42] The rarity of MPAL with the capability to switch lineages under pressure (treatment) defines the challenges in treating MPAL. MPAL has a poor prognosis and worse outcomes than standard-risk AML or ALL.[43] A meta-analysis inclusive of international case reports and small case series from a variety of pathology and clinical journals identified over a thousand patients diagnosed with MPAL using either the EGIL or WHO criteria.[44] In this large analysis, patients beginning therapy with an AML-style induction regimen were significantly less likely to achieve a complete remission and nearly twice as likely to die of their disease as those receiving an ALL-style induction. The currently recommended treatment approach for MPAL in both pediatric and adult patients is induction therapy with an ALL regimen.[43,45] Patients with MPAL with *BCR*::*ABL1* may

ultimately benefit from addition of a tyrosine kinase inhibitor.[46] Clinical outcomes of children with MPAL tend to be better compared to those of adults with MPAL, with a higher OS and fewer relapses; however, outcomes for acute leukemia are in general better in children than in adults.[15,47] The debate on the most appropriate induction regimen remains unresolved over the controversy whether initial therapy should be based on immunophenotype, cytogenetics, or molecular biology.

Lineage Switch

Immunophenotypic properties of MPAL are not stable over time: both variable proportions of different lineages and phenotypic alterations are known as lineage switch. Most cases of lineage transformation involve a switch from ALL to AML, and a retrospective review can often reveal the presence of an unrecognized or underappreciated malignant subclonal population present in the initial specimen, which displayed more chemoresistance and emerged after eradication of the chemosensitive dominant clone.[48]

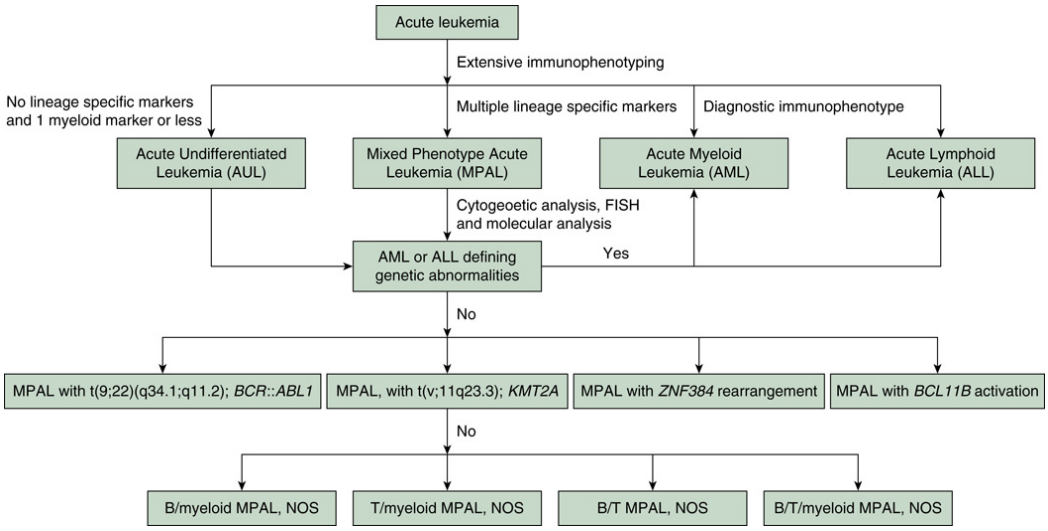

FIGURE 42-3 Proposed acute leukemias of ambiguous lineage (ALAL) classification scheme.

The selective pressure brought on by specific therapies can influence these transformations, especially in MPAL (e.g., resultant AML after the use of B-cell specific therapy such as blinatumomab). However, frank ALL-to-AML lineage switch must be distinguished from the B-monocytic transition commonly seen in ALL with *DUX4*-rearrangements and other alterations early in therapy in which such changes do not affect prognosis with continued ALL therapy.[49]

Differential Diagnosis

The primary challenge in diagnosing MPAL is ruling out cytogenetically defined neoplasms that demonstrate an MPAL-like immunophenotype (**Fig. 42-3**). A careful review of patient history is thus essential. For example, patients with a history of chronic myeloid leukemia (CML) who develop blast crisis with mixed phenotype should not be diagnosed as MPAL with t(9;22). Similarly, patients with CML in blast crisis with lineage switch are also

excluded from this category. AML with t(8;21)(q22;q22.1) often expresses B-lineage markers, including CD19, PAX5, and CD79a, and care should be taken to not diagnose MPAL in this setting. Cytogenetic abnormalities and molecular findings diagnostic of AML-MRC or AML with myelodysplasia-related mutation[50] also preclude diagnosis of MPAL, but such a diagnosis could be modified in such a way as to highlight the immunophenotype (i.e., AML with myelodysplasia-related gene mutations and a mixed [B/myeloid] immunophenotype). Myeloid/lymphoid neoplasms with eosinophilia and *FGFR1* rearrangement are a group of hematopoietic neoplasms that can present as acute leukemias expressing mixed lineage markers, but they should not be diagnosed as MPAL at initial presentation.

ETP lymphoblastic leukemia is characterized by expression of CD7, weak or absent CD5, one or more myeloid/stem cell markers other than MPO, and cytoplasmic CD3.[51] The co-expression of myeloid markers and CD3 makes distinguishing ETP-ALL from T/myeloid MPAL problematic; molecular data blur the distinction between these entities, and the distinction is increasingly artificial: The *BCL11B* cases have a strict ETP immunophenotype with negativity of CD5 but variable cCD3+/– or MPO+/– resulting in variable classification. Moreover, emerging work is showing the biology of the immature leukemias are explained by diverse genomic alterations converging on a conserved set of stem cell genes: *HOXA9, HOXA13, ETV6, MED12,* and *ZNF36L2*. These cases have homogeneous gene expression but variable ambiguity: ETP, MPAL, or not (i.e., non-ETP T-ALL).

Pearls and Pitfalls

Pearls

- MPAL is a heterogenous group of leukemias that are genetically, immunophenotypically, and clinically diverse.
- ALAL includes biologically diverse leukemias that fail to show commitment to either the myeloid or lymphoid lineages or show evidence of commitment to more than one lineage. Cases in the former group are referred to as AUL, and those in the latter are identified as MPAL.
- A diagnosis of MPAL is based on the presence of two disparate populations of blasts, each of which demonstrates a distinct and lineage-specific phenotype, or a single population of blasts expressing markers specific to more than one lineage.

Pitfalls

- In cases with separate blast populations, each population needs to be classified according to AML and ALL criteria.
- Gene mutations found within MPAL are a mixture of those commonly seen in both AML and ALL and, as such, cannot be used to define a lineage.
- Immunophenotypic properties of MPAL are not stable over time; both variable proportions of different lineages and phenotypic alterations are known as lineage switch.

Conclusion

Introduction

The International Consensus Classification (ICC, 2022) of myeloid neoplasms[1] is primarily used in this book in comparison with the revised 4th edition of the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues first published in 2016.[2] At the time of this writing, a 5th edition of the WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues has been proposed but is not yet final.[3] The principles of the ICC 2022 have been described elsewhere,[4,5] and the process for developing this consensus classification is summarized in **Chapter 12**. Briefly, the ICC 2022 follows the approach of the 3rd, 4th, and revised 4th editions of the WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, with changes informed by input from a Clinical Advisory Committee (CAC). This approach relies on a combination of clinical, morphologic, immunophenotypic, genetic, and other biological features to define specific disease entities—a logical approach similar to that followed by a clinician and a pathologist working together to reach a diagnosis in a patient suspected of having a myeloid neoplasm. The relative contribution of each feature varies, depending on the case. Only through familiarity with the classification system and with the criteria for each entity can the appropriate studies be chosen to arrive at an accurate diagnosis in an expeditious manner. Although perhaps overused as an example

of the prototype for the classification of myeloid neoplasms, chronic myeloid leukemia (CML) symbolizes the utility of the prior WHO and current ICC 2022 approaches. This leukemia is recognized mainly by its clinical and morphologic features and is consistently associated with a specific genetic abnormality, the *BCR*::*ABL1* fusion gene, which leads to the production of a constitutively activated protein tyrosine kinase that interacts with a number of different cellular pathways to influence the proliferation, survival, and differentiation of neoplastic cells. The protein is sufficient to cause the leukemia, but it also provides a target for therapy that has prolonged the lives of thousands of patients with this disease.[6] The diagnosis of CML, however, is not based on any single parameter. There are other myeloid leukemias that mimic its clinical presentation and morphology, and the *BCR*::*ABL1* fusion is seen not only in CML but also in some cases of de novo acute lymphoblastic leukemia, acute myeloid leukemia (AML), and mixed phenotype acute leukemia (MPAL). Thus, CML is a perfect model for the integration of all pieces of relevant information to define an entity in a classification scheme. Furthermore, there are still mysteries regarding CML, so there is still more to learn (see **Chapter 47**).

As the focus in all neoplasms turns increasingly to the genetic infrastructure of malignant cells and to molecular abnormalities that may be targets for therapeutic agents, it is only natural that more genetic and molecular data are incorporated into the diagnostic algorithms or nomenclature of classification schemes. The 2001 3rd edition of the WHO classification included, for the first time in any widely used system, genetic information as criteria for the diagnosis of not only CML but also some subtypes of AML.[7] By the time the

2008 4th edition and 2016 revised 4th edition of the WHO classification were published, a number of significant genetic abnormalities were discovered that are associated with subgroups of myeloid neoplasms or with specific disease entities within the subgroups. Since that time, an even larger number of genetic and epigenetic events associated with myeloid neoplasms have been described, making an approach that uses these data for both classification and prognostication more challenging. In some instances, such as myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions, the genetic defect (coupled with the morphology and clinical findings) is the major criterion for naming the disease and for selecting specific targeted therapy (see **Chapter 50**). In other instances, such as the *BCR*::*ABL1*-negative myeloproliferative neoplasms (MPNs) that are often but not invariably associated with the *JAK2* V617F mutation, the presence of the genetic defect is an objective criterion that identifies the myeloid proliferation as neoplastic. Additional criteria are necessary to define the specific disease associated with the mutated *JAK2* and to distinguish it from other MPNs that share the same mutation (see **Chapter 47**). Therefore, although the ICC 2022 incorporates an increased number of genetic abnormalities, a multidisciplinary approach is still required for the classification of myeloid neoplasms. This multidisciplinary approach succeeds in defining many distinct disease entities that cannot be adequately identified by relying on morphology or clinical features alone. Such a limited approach to myeloid neoplasms is no longer adequate, and a diagnosis is not complete in many cases until the results of all studies have been correlated, often requiring amended pathology reports.

New entities and new diagnostic criteria for old entities in the ICC 2022 are based mainly on published clinical and scientific studies that have been extensively quoted and their significance widely acknowledged. However, to accommodate data that have not yet "matured," the classification continues to have a number of "provisional entities" to include diseases that are clinically or scientifically important and should be considered in the classification but for which additional studies are needed to clarify their significance. Some previous provisional entities have been refined in the current classification and are now incorporated as full entities, and their presence emphasizes that the classification is ever-changing.

Evaluation of Myeloid Neoplasms

Myeloid neoplasms are serious, often life-threatening disorders, and their diagnosis requires a concerted effort by the clinician and the pathologist to thoroughly and carefully evaluate the clinical, morphologic, immunophenotypic, and genetic data. Too often, a diagnosis is based on insufficient knowledge of the clinical and laboratory information and, particularly, on inadequate diagnostic specimens. Although the proper collection and processing and testing of blood and bone marrow specimens are addressed elsewhere,[8] **Box 43-1** emphasizes additional guidelines in assessing specimens from patients suspected of having myeloid neoplasms. One rule of thumb is that morphology is a key criterion in the diagnosis of all myeloid neoplasms, even those in which there is a closely associated genetic defect or characteristic immunophenotypic

profile. If the specimen is not adequate to evaluate morphologically, a new specimen should be obtained.

The ICC 2022 and prior WHO criteria apply to initial peripheral blood and bone marrow specimens obtained before any definitive therapy (including growth factor therapy) for the suspected hematologic neoplasm. Morphologic, cytochemical, and immunophenotypic features are used to establish the lineage of the neoplastic cells and to assess their maturation. The blast percentage remains a practical tool for subcategorizing myeloid neoplasms and judging their progression, but use of the blast percentage has evolved in the ICC 2022. Traditionally, a myeloid neoplasm with 20% or more blasts in the blood or bone marrow is considered AML when it occurs de novo or evolution to AML if it occurs in the setting of a previously diagnosed myelodysplastic syndrome (MDS), MDS/MPN, or blast transformation of a previously diagnosed MPN. For de novo disease, a diagnosis of AML can now be made with blast counts of 10% or more in the setting of most recurring genetic abnormalities. Furthermore, a gradually increasing blast count at any level is usually associated with disease progression. A new category of MDS/AML with blasts between 10% and 19% is introduced in the ICC 2022 based on biological similarities between cases independent of blast cell count.[9] This new category applies to cases that have evolved from MDS and to de novo cases not associated with an AML-defining genetic abnormality, including cases with MDS-related gene mutations, *TP53* mutations, and MDS-related cytogenetic abnormalities. Blast percentages should be derived, when possible, from 200-cell leukocyte differential counts of the peripheral blood smear and 500-cell differential counts of all nucleated bone marrow

cells on cellular bone marrow aspirate smears stained with Wright-Giemsa or a similar stain. Blasts are defined with the criteria proposed by the International Working Group on Morphology of Myelodysplastic Syndrome[10] and as outlined in **Box 43-1**. Determination of the blast percentage by flow cytometry assessment of CD34-positive cells is not recommended as a substitute for visual inspection; not all leukemic blasts express CD34, and hemodilution and other processing artifacts can produce misleading results. The detection of more CD34-positive cells by flow cytometry than expected from the morphologic evaluation, however, requires a reassessment of both specimens to resolve the discrepancy. CD34 immunohistochemistry might also play a valuable role in such circumstances. This reassessment may identify unusually small blasts that were initially confused with lymphocytes, or it may show erythroid hyperplasia that, after red blood cell lysis of the flow cytometry specimen, resulted in a falsely elevated CD34 count.

For acute leukemia, multiparameter flow cytometry (see **Chapter 4**) with CD45 versus side scatter gating is the method of choice for determining the blast lineage and for detecting aberrant antigenic profiles that may prove useful for disease monitoring. **Figure 43-1** demonstrates antigens expressed at various levels of normal myeloid differentiation. These can be detected by flow cytometry or by immunohistochemistry on bone marrow biopsy specimens. However, asynchronous expression of maturation-associated antigens by neoplastic myeloid cells is not uncommon and is best determined by flow cytometric analysis.[11]

Although a bone marrow biopsy is not required for diagnosis in every patient with a myeloid neoplasm (particularly if the patient is

frail and there are few treatment options available), an adequate biopsy provides the most accurate assessment of marrow cellularity, topography, stromal changes, and maturation patterns of the various lineages, and it can be invaluable in detecting measurable residual disease after therapy. In addition, the biopsy provides material for the immunohistochemical detection of antigens that can be diagnostically and prognostically useful, particularly if marrow aspirate smears are poorly cellular.[12]

Box 43-1 Evaluation of Myeloid Neoplasms

AML, Acute myeloid leukemia; *MPN,* myeloproliferative neoplasm; *NOS,* not otherwise specified.

Specimen Requirements

- Peripheral blood and bone marrow specimens obtained before any definitive therapy for the suspected myeloid neoplasm
- Peripheral blood and cellular marrow aspirate smears or touch preparations stained with Wright-Giemsa or similar stains
- Bone marrow biopsy at least 1.5 cm long and at right angles to the cortical bone for all cases, if feasible
- Bone marrow specimens for complete cytogenetic analysis and, when indicated, for flow cytometry, with an additional specimen cryopreserved for molecular genetic studies; the latter studies should be performed on the basis of initial karyotypic, clinical, morphologic, and immunophenotypic findings

Assessment of Blasts in Peripheral Blood and Bone Marrow Specimens

- Determine the blast percentage in peripheral blood and cellular bone marrow aspirate smears by visual inspection.
- Count myeloblasts, monoblasts, promonocytes, and megakaryoblasts (but not dysplastic megakaryocytes) as blasts when determining blast percentage for diagnosis of AML or blast transformation; count abnormal promyelocytes as “blast equivalents” in acute promyelocytic leukemia.
- Proerythroblasts are not counted as blasts except in rare instances of pure erythroleukemia.
- Flow cytometric assessment of CD34-positive cells is not recommended as a substitute for visual inspection; not all blasts express CD34, and artifacts introduced by specimen processing may result in erroneous estimates.
- If the aspirate is poor or marrow fibrosis is present, immunohistochemistry on biopsy sections for CD34 may be informative if blasts are CD34 positive.

Assessment of Blast Lineage

- Multiparameter flow cytometry should be performed; the panel should be sufficient to determine lineage and aberrant antigen profile of the neoplastic population.
- Cytochemistry, such as myeloperoxidase or non-specific esterase, may be helpful, particularly in AML, NOS, but it is not essential in all cases.

- Immunohistochemistry on bone marrow biopsy may be helpful; many antibodies are now available for the recognition of myeloid and lymphoid antigens.

Assessment of Genetic Features

- Complete cytogenetic analysis of bone marrow at initial diagnosis
- Additional studies, such as fluorescence in situ hybridization (FISH) or reverse transcriptase polymerase chain reaction (RT-PCR), should be guided by clinical, laboratory, and morphologic information
- Mutational studies for *JAK2,* followed by *CALR* and *MPL,* if indicated, should be sought in *BCR*::*ABL1*-negative MPNs
- Mutation panels that include *a broad panel of genes* should be performed on new cases of AML and MDS and should be considered in other case types

Correlation and Reporting of Data

- All data should be assimilated into one report that states the diagnosis and what classification was used.

A complete cytogenetic analysis of bone marrow cells is essential during the initial evaluation for establishing a baseline karyotype; thereafter, repeated analyses are recommended as needed to judge the response to therapy or to detect genetic evolution. Additional genetic studies should be guided by the results of the initial karyotype and by the suspected diagnosis based on the clinical,

morphologic, and immunophenotypic studies. In some cases, reverse transcriptase polymerase chain reaction (RT-PCR), fluorescence in situ hybridization (FISH), or RNA sequencing methods may detect variants of well-recognized cytogenetic abnormalities or submicroscopic abnormalities not detected by routine karyotyping, such as the *FIP1L1*::*PDGFRA* rearrangement found in some myeloid neoplasms associated with eosinophilia[13] or the *BCR*::*ABL1* fusion in about 5% to 10% of cases of CML when the Philadelphia (Ph) chromosome is not found by routine cytogenetic studies. Molecular studies may also prove useful in emergency situations while awaiting routine cytogenetic results, such as detection of *PML*::*RARA* fusion in cases of acute promyelocytic leukemia. In addition, gene mutations are important diagnostic and prognostic markers in myeloid neoplasms (as will become apparent in the chapters that follow). These include mutations of *JAK2, CALR, MPL,* and *KIT* in MPN[14-21]; *ASXL1, TET2, NRAS, KRAS, NF1, RUNX1,* and *PTPN11* in MDS/MPN[22-29]; *BCOR, CEBPA, DNMT3A, EZH2, FLT3, KIT, NPM1, RUNX1, SF3B1, SRSF2, STAG2, TP53, U2AF1, WT1,* and *ZRSR2,* in AML[1,30-35]; *ASXL1, TP53, EZH2, ETV6,* and *RUNX1* in MDS[36]; and *GATA1*[37] in myeloid proliferations associated with Down syndrome. In many cases, the mutational analysis should be done up front in the evaluation of diagnostic specimens; for example, in suspected cases of *BCR*::*ABL1*-negative MPNs, detecting the *JAK2* V617F mutation can substantiate the diagnosis of a clonal myeloproliferation. Gene panels are now widely available, and their use up front has become the standard of care for all new leukemia specimens.

International Consensus Classification

The ICC 2022 of myeloid neoplasms is shown in **Box 43-2**. The term *myeloid* includes all cells belonging to the granulocytic (neutrophil, eosinophil, basophil), monocyte/macrophage, erythroid, megakaryocytic, and mast-cell lineages.

In general, the diseases are stratified into neoplasms comprising precursor cells (blasts) with minimal, if any, maturation (i.e., AML) and those in which there is maturation, either effective or ineffective, in the myeloid lineages. Each subgroup includes entities that are clinically or nosologically relevant and defined with ICC 2022 principles. **Table 43-1** lists the major subgroups of myeloid neoplasms and their characteristics at diagnosis. Each subgroup is described in detail in the upcoming chapters, but some brief comments regarding the rationale for the classification and the major changes from previous schemes are provided here.

Myeloproliferative Neoplasms

In previous classification schemes used for MPNs,[7] detection of the Ph chromosome or *BCR*::*ABL1* fusion gene was used to confirm the diagnosis of CML. The remaining subtypes of *BCR*::*ABL1*-negative MPNs, including polycythemia vera, primary myelofibrosis, and essential thrombocythemia, were diagnosed by somewhat complicated algorithms that included non-specific clinical and laboratory features intended to distinguish subtypes of MPN from one another and from reactive bone marrow hyperplasia that can mimic MPN.[38] However, the discovery in 2005 of the *JAK2* V617F and similar mutations in virtually all cases of polycythemia vera and in 50% of cases of essential thrombocythemia and primary

myelofibrosis revolutionized, yet also simplified, the diagnostic criteria for these neoplasms.[14,15,39-41] Since that time, the detection of mutations in *JAK2* exon 12, *MPL,* and more commonly, *CALR* have been discovered in many cases of *JAK2*-negative MPN.[18,20,21,42] Although not specific for any MPN, detection of one of these activating mutations identifies the case in question as clonal and thus eliminates a number of diagnostic procedures used to distinguish MPNs from reactive hyperplasia. Unfortunately, for the cases of essential thrombocythemia and primary myelofibrosis that lack a mutation, the distinction between a neoplastic and a reactive process occasionally remains problematic because absence of *JAK2* V617F or a similar activating mutation does not exclude an MPN. In addition, even when a mutation is present, it does not distinguish one MPN from another (except that polycythemia vera is only associated with *JAK2* mutations), so additional criteria are necessary. In previous schemes, histopathology and morphologic features played only a minor role in substantiating the diagnosis of an MPN and distinguishing the various subtypes, and hematologic data or clinical information was more important; but the past decade has brought better characterization and more widespread recognition of the histologic features associated with the MPN subtypes, and specific histopathologic features were included as diagnostic parameters in the prior WHO and current ICC 2022 schemes. Therefore, the diagnostic algorithms for MPNs now include clinical, hematologic, genetic, and histologic data to accurately identify and classify the various subtypes.

Box 43-2 2022 International Consensus Classification of Myeloid Neoplasms

Myeloproliferative Neoplasms

Chronic myeloid leukemia
Polycythemia vera
Essential thrombocythemia
Primary myelofibrosis
Early/prefibrotic primary myelofibrosis
Overt primary myelofibrosis
Chronic neutrophilic leukemia
Chronic eosinophilic, not otherwise specified
Myeloproliferative neoplasm, unclassifiable

Myeloid/Lymphoid Neoplasms With Eosinophilia and Tyrosine Kinase Gene Fusions

Myeloid/lymphoid neoplasm with *PDGFRA* rearrangement
Myeloid/lymphoid neoplasm with *PDGFRB* rearrangement
Myeloid/lymphoid neoplasm with *FGFR1* rearrangement
Myeloid/lymphoid neoplasm with *JAK2* rearrangement
Myeloid/lymphoid neoplasm with *FLT3* rearrangement
Myeloid/lymphoid neoplasm with *ETV6*::*ABL1*

Mastocytosis

Myelodysplastic/Myeloproliferative Neoplasms

Chronic myelomonocytic leukemia
Clonal cytopenia with monocytosis of undetermined significance
Clonal monocytosis of undetermined significance
Atypical chronic myeloid leukemia
Myelodysplastic/myeloproliferative neoplasm with thrombocytosis and *SF3B1* mutation

Myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis, not otherwise specified
Myelodysplastic/myeloproliferative neoplasm, not otherwise specified

Premalignant Clonal Cytopenias and Myelodysplastic Syndromes

Clonal cytopenia of undetermined significance
Myelodysplastic syndrome with mutated *SF3B1*
Myelodysplastic syndrome with del(5q)
Myelodysplastic syndrome with mutated *TP53*
Myelodysplastic syndrome, not otherwise specified (MDS, NOS)
- MDS, NOS without dysplasia
- MDS, NOS with single lineage dysplasia
- MDS, NOS with multilineage dysplasia

Myelodysplastic syndrome with excess blasts
Myelodysplastic syndrome/acute myeloid leukemia (MDS/AML)
- MDS/AML with mutated *TP53*
- MDS/AML with myelodysplasia-related gene mutations
- MDS/AML with myelodysplasia-related cytogenetic abnormalities
- MDS/AML, not otherwise specified

Pediatric and/or Germline Mutation-Associated Disorders

Juvenile myelomonocytic leukemia

Juvenile myelomonocytic leukemia-like neoplasms
Noonan syndrome-associated myeloproliferative disorder
Refractory cytopenia of childhood
Hematologic neoplasms with germline predisposition

Acute Myeloid Leukemias

Acute promyelocytic leukemia (APL) with t(15;17)(q24.1;q21.2)/*PML*::*RARA*
APL with other *RARA* rearrangements
AML with t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*
AML with t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*
AML with other *KMT2A* rearrangements
AML with t(6;9)(p22.3;q34.1)/*DEK*::*NUP214*
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2;MECOM(EVI1)*
AML with other *MECOM* rearrangements
AML with other rare recurring translocations
AML with t(9;22)(q34.1;q11.2)/*BCR*::*ABL1*
AML with mutated *NPM1*
AML with in-frame bZIP *CEBPA* mutations
AML and MDS/AML with mutated *TP53*
AML and MDS/AML with myelodysplasia-related gene mutations
AML and MDS/AML with myelodysplasia-related cytogenetic abnormalities
AML and MDS/AML, not otherwise specified (NOS)

Myeloid sarcoma

Myeloid sarcoma

Myeloid Proliferations Associated With Down Syndrome

Acute Leukemia of Ambiguous Lineage

Mixed phenotype acute leukemia (MPAL) with defining genetic alterations

MPAL with *BCR*::*ABL1*

MPAL with t(v;11q23.3): *KMT2A* rearranged

MPAL with *BCL11B* activation

MPAL with defining immunophenotypic changes

B/Myeloid MPAL

T/Myeloid MPAL

B/T MPAL

Acute undifferentiated leukemia

Acute leukemia of ambiguous lineage, NOS

Myeloid/Lymphoid Neoplasms With Eosinophilia and Tyrosine Kinase Gene Fusions

Synonyms and Related Terms

WHO revised 4th edition: Myeloid/Lymphoid Neoplasms with Eosinophilia and Rearrangement of *PDGFRA, PDGFRB, FGFR1* or with *PCM-JAK2*

WHO proposed 5th edition: Myeloid/Lymphoid Neoplasms with Eosinophilia and Tyrosine Kinase Gene Fusions

Some myeloid neoplasms associated with eosinophilia, including cases formerly designated chronic eosinophilic leukemia (CEL) or hypereosinophilic syndrome, are caused by abnormalities in genes that encode the α or β forms of platelet-derived growth factor receptor (PDGFR) and result in its constitutive activation. Rearrangements of *PDGFRB* were first recognized in cases variably diagnosed as chronic myelomonocytic leukemia (CMML) with eosinophilia or as CEL,[43-46] whereas rearranged *PDGFRA* was found to be involved in CEL and in cases previously considered hypereosinophilic syndrome.[13] Rearrangements of *FGFR1* have also been implicated in myeloproliferations with prominent eosinophilia, such as 8p11.2 myeloproliferative syndrome.[47] However, patients with *FGFR1* rearrangements may initially have T-lymphoblastic or B-lymphoblastic leukemia/lymphoma associated with prominent tissue eosinophilia that later evolves to a myeloid neoplasm with eosinophilia, or vice versa.[47,48] Rare cases associated with *PDGFRA* rearrangements initially had a lymphoblastic neoplasm associated with eosinophilia.[49] Other gene fusions resulting in similar clinical disorders have been described, most notably involving *JAK2, FLT3, ETV6* and *ABL1*.[50,51] These somewhat varied clinical and morphologic presentations—CMML with eosinophilia, CEL, lymphoblastic leukemia/lymphoma with eosinophilia—argued for the creation of a separate category defined by the genetic lesions rather than dispersing the entities in multiple different subgroups throughout the classification. The creation of this subgroup—previously termed myeloid and lymphoid neoplasms with eosinophilia and rearrangements of *PDGFRA, PDGFRB,* or *FGFR1* or with *PCM1*::*JAK2* but now updated to myeloid and lymphoid

neoplasms with eosinophilia and tyrosine kinase gene fusions—is a practical way to emphasize that patients with these rearrangements may respond to tyrosine kinase inhibitor therapies (see **Chapter 50**).

Table 43-1

AML, Acute myeloid leukemia; *BM,* bone marrow; *CML,* chronic myeloid leukemia, *BCR*::*ABL1* positive; *ET,* essential thrombocythemia; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *PMF,* primary myelofibrosis; *PTKs,* protein tyrosine kinases; *WBC,* white blood cell.

* Approximately 50% of patients with rearrangements of *FGFR1* initially are seen with a T-lymphoblastic or, less commonly, B-lymphoblastic leukemia/lymphoma. Rare cases of *PDGFRA* rearrangements may initially have lymphoblastic leukemia/lymphoma.

Myelodysplastic/Myeloproliferative Neoplasms

The MDS/MPN category was introduced in the WHO 3rd edition to include myeloid neoplasms with clinical, laboratory, and morphologic features that overlap MDS and MPN. Most of the entities included in this category have elevated white blood cell counts, anemia or thrombocytopenia, and variable amounts of morphologic dysplasia. This disease group included CMML, atypical CML, juvenile myelomonocytic leukemia, and a newer entity within the MDS/MPN unclassifiable group: refractory anemia with ring sideroblasts and thrombocytosis (subsequently termed MDS/MPN

with ring sideroblasts and thrombocytosis; MDS/MPN-RS-T). Many cases of MDS/MPN-RS-T had mutations of *JAK2* or other MPN-associated genes and mutations of *SF3B1,* common in MDS with ring sideroblasts,[52] supporting the mixed myelodysplastic/myeloproliferative features of the disease. The ICC 2022 further refines this category of MDS/MPN to include (1) myelodysplastic/myeloproliferative neoplasm with *SF3B1* mutation and thrombocytosis and (2) myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis, not otherwise specified (NOS) (for cases without *SF3B1* mutations). The proposed WHO 5th edition only includes the former disease group, and it is unclear at the time of this writing where cases without *SF3B1* mutations would reside in that classification. A few cases of CMML and atypical CML have been reported to demonstrate *JAK2* V617F mutations,[40,41,53] but when mutations are detected in CMML and atypical CML, they do not occur in isolation, i.e., mutations in other genes are also present.[54-57] In juvenile myelomonocytic leukemia, more than 80% of patients demonstrate mutually exclusive RAS pathway mutations.[22,24,57] Approximately 30% to 40% of cases of CMML and atypical CML also exhibit *NRAS* or *KRAS* mutations.[25-27,58] The ICC 2022 recognizes the unique features of juvenile myelomonocytic leukemia (JMML) and related disorders, often with germline gene mutations, and now groups them in a new section of pediatric disorders and/or germline mutation-associated disorders. The proposed WHO 5th edition moves JMML to the myeloproliferative disorder category, which seems inappropriate for a neoplasm so different from the other adult preponderant MPNs.

Myelodysplastic Syndromes

Synonyms and Related Terms

WHO revised 4th edition: Myelodysplastic Syndromes
WHO proposed 5th edition: Myelodysplastic Neoplasms

Most cases of MDS are readily recognized by the characteristic findings of cytopenia in an older adult associated with morphologic dysplasia in the blood and bone marrow, with or without an increase in the number of blasts in the blood or bone marrow. Nearly 50% of cases have a cytogenetic lesion at the time of diagnosis that is characteristically associated with loss of genetic material, through either chromosomal loss or epigenetic phenomena, and the majority have gene mutations, even when a relatively small mutation panel is used.[36] In most cases, subclassification of MDS is readily achieved by assessing the number of lineages that are dysplastic and accurately counting the number of blasts in the blood and bone marrow—essentially a grading system. Still, MDS remains one of the most challenging of the myeloid neoplasms for diagnosticians. In particular, problems arise when the clinical and laboratory findings suggest MDS but the morphologic findings are inconclusive; when secondary or transient dysplasia caused by nutritional deficiencies, medications, toxins, growth factor therapy, inflammation, or infection mimics the dysplasia of MDS; or when marrow hypocellularity or myelofibrosis obscures the underlying disease process.[12,59-62] The ICC 2022 provides guidelines for the minimal morphologic criteria for the diagnosis of MDS, provides criteria for clonal cytopenia of undetermined significance and other premalignant clonal cytopenias, and has incorporated gene mutation studies into the classification by adding new categories of MDS with

mutated *SF3B1* (usually with ring sideroblasts) and MDS with mutated *TP53* (see **Chapter 44**). The ICC 2022 introduces a category of MDS/AML for some patients with 10% to 19% peripheral blood or bone marrow blasts, which replaces many cases of adult MDS with excess blasts-2. This category does not apply to children with MDS and 10% to 19% blast cells. The WHO 4th edition introduced a new, provisional entity, refractory cytopenia of childhood, for children with MDS who have cytopenia, multilineage dysplasia, less than 2% blasts in the blood, and less than 5% blasts in the bone marrow. This provisional clinicopathologic entity remains in the classification, but it is not currently clear if it actually represents a neoplastic process in most cases; it is now included in the section on pediatric disorders and/or germline mutation-associated disorders. Refractory cytopenia of childhood is renamed childhood MDS with low blasts in the proposed WHO 5th edition.

Acute Myeloid Leukemia

The 2001 WHO 3rd edition opened the door to the formal inclusion of genetic abnormalities in the diagnostic algorithms for AML. The genetic defects included were mainly chromosomal translocations involving transcription factors associated with characteristic morphologic and clinical features, thus forming distinct clinicopathologic-genetic entities. By the WHO 4th edition in 2008, it had become accepted that, in many cases of AML, multiple genetic lesions—including not only microscopically detectable chromosomal rearrangements or numerical abnormalities but also submicroscopic gene mutations—cooperate to establish the leukemic process and influence its morphologic and clinical characteristics.

Rearrangements or mutations of genes that normally encode transcription factors important for myeloid differentiation and maturation, such as *RUNX1, RARA,* or *NPM1,* may result in impaired maturation of leukemic cells, whereas mutations of genes involved in signal transduction pathways, such as *FLT3, JAK2, RAS,* or *KIT,* may be required for the proliferation or survival of the neoplastic clone.[63] It is now understood that gene mutations are even more complicated than assumed in that simple two-group approach, and numerous cooperating mutations occur in AML.[35] Often, the combination of these abnormalities leads to a leukemia with distinct clinical and morphologic findings and distinct survival characteristics. Discovery of the role of genetic mutations in leukemia was initially focused on the largest cytogenetic subgroup of patients with AML—those with normal karyotypes—and an entirely new understanding and subclassification of this group emerged.[30] Gene mutations demonstrate importance across other genetic AML types, however, and such studies are now indicated for all AML types.[35,64]

With the ICC 2022, AML classification moves to a more pronounced genetic approach with creation of new categories with recurring genetic abnormalities and gene mutations. AML with *TP53* is a high-risk group, not included in the proposed WHO 5th edition, but it naturally follows the categories of MDS and MDS/AML with this gene mutation. Of note, our understanding of AMLs with myelodysplasia-associated changes has grown over the last 2 decades, and both the ICC 2022 and the proposed WHO 5th edition move toward cytogenetic and molecular genetic definitions of these disorders that no longer include morphologic changes of non-blast

cells. The ICC 2022 also clearly defines cases by genetic changes first, with qualifiers used to note prior MDS, MDS/MPN, or cytotoxic therapy and qualifiers to note the presence of germline gene abnormalities.

The subgroup AML, NOS (now termed AML defined by differentiation in the proposed WHO 5th edition), remains largely defined by morphology; no distinct clinical, immunophenotypic, or genetic disease entities are currently recognized in this category. Similar to diffuse large B-cell lymphoma, NOS and peripheral T-cell lymphoma, NOS, AML, NOS represents a heterogeneous group of disorders. The number of cases falling into this group has decreased with the addition of new specific AML genetic entities.

Acute Leukemias of Ambiguous Lineage

Although they are not truly myeloid neoplasms, the diagnostic approach to acute leukemias of ambiguous lineage is similar to that of the myeloid neoplasms, requiring correlation of morphologic features with cytogenetic, molecular, genetic, and immunophenotypic results. In particular, the ICC 2022 and proposed WHO 5th edition define criteria for the diagnosis of acute leukemias of mixed phenotype, which are now termed mixed phenotype acute leukemia, or MPAL. Genetic categories of MPAL are defined to emphasize the biological and clinical importance of *BCR*::*ABL1* and *KMT2A* translocations and newly added *ZNF384* and *BCL11B* activation[65]; in these disorders, these features probably define clinical disease entities better than immunophenotyping studies alone (see **Chapter 42**).

Pediatric Disorders and/or Germline Mutation–Associated Disorders

A major addition to the 2016 revised 4th edition of the WHO classification was a section on germline predisposition to myeloid neoplasms (see **Chapter 45**), which may be identified in patients of all ages. These patients may have thrombocytopenia that progresses to myeloid neoplasms or presents as de novo cases of AML or MDS.[66] Whereas many of the germline mutations in these patients are similar to the ones acquired sporadically in other patients with AML or MDS, the detection of a germline mutation should result in screening of family members for predisposition to these neoplasms. The ICC 2022 expanded the categories of hematologic neoplasms with germline predisposition and also more clearly separated JMML from adult MDS/MPN and refractory cytopenia of childhood from MDS. In addition to JMML, which is now defined by the presence of RAS pathway mutations, the ICC 2022 provides criteria for JMML-like neoplasms that do not have such mutations and criteria for Noonan syndrome–associated myeloproliferative disorder.

Conclusion

There will continue to be new information about many of the myeloid neoplasms, even as this text is published, and perhaps even new disease entities will have been proposed during that time. To continue to be useful in practice and in the evaluation of data from clinical trials and laboratory investigations, any classification must be continually reviewed and updated. Conversely, new information needs to "mature" and to be confirmed in large studies by numerous investigators to be widely accepted and integrated into daily practice.

Therefore, although we eagerly await new data on the myeloid neoplasms discussed in this volume, it is hoped that the principles of classification exemplified in the CAC approach used for the ICC 2022 will endure.

Etiology and Pathogenesis

CONCLUSION

Incidence

Myelodysplastic syndrome (MDS) is a disease predominantly of the elderly; its incidence increases exponentially with age, with a noticeable rise beginning in the fifth decade and a median age estimated at approximately 76 years.[1-6] MDS is more common in men, with a male-to-female ratio approaching 2:1, although one subtype **(MDS with deletion 5q)** more commonly affects women. Though the incidence of MDS in children and young adults is in the range of only 0.05 to 0.4 cases per 100,000 per year,[7-11] its incidence exceeds 25/100,000 cases per year by the age of 70 years and rises to more than 36/100,000 cases per year in individuals older than 80 years.[2-5,8-11] However, there are several caveats in interpreting these epidemiologic data: (1) MDS may be difficult to diagnose, and some cases may be confused with other diseases.[12] (2) Some elderly patients receive only supportive treatment for presumed MDS, without a diagnostic workup or an explicit diagnosis. (3) In the past, there has been disagreement as to whether MDS is truly neoplastic, and many national cancer epidemiology registries have failed to record cases of MDS. However, according to current concepts, MDS is by definition a myeloid neoplasm.

Synonyms and Related Terms

The proposed 5th edition of the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues changed “myelodysplastic syndrome” to “myelodysplastic neoplasm,” while retaining the “MDS” abbreviation.

Clinical Features

MDS typically presents with symptoms and signs related to single or multiple peripheral blood cytopenias: anemia (weakness, pallor, fatigue), thrombocytopenia (petechiae, bleeding), or neutropenia (recurrent infections).[13-15] Occasionally, cases are recognized when asymptomatic cytopenias are noted during a routine complete blood count or when increased blasts, dysplastic morphology, or clonal cytogenetic abnormalities are identified in studies of peripheral blood or bone marrow obtained for other purposes.

Granulocytic or myeloid sarcomas (mass-forming collections of myeloblasts) can present as extramedullary tumors in patients with a history of MDS. If confirmed histologically, they are considered to represent transformation to acute myeloid leukemia (AML), even if the bone marrow myeloblast count remains below 20%. Splenomegaly is uncommon in MDS and, if present, tends to suggest an alternate diagnosis. Skin infiltrates of atypical myeloid and/or histiocytoid-looking cells (including Sweet’s syndrome and so-called “histiocytoid Sweet’s syndrome” or “specific lesions”) are described rarely in MDS.[16] Some investigators have proposed the term “myelodysplasia cutis” to encompass cases of perivascular atypical histiocytoid-appearing cells with elongated nuclei, likely representing

dysplastic granulocytes, occurring in skin biopsies of patients with MDS.[17,18] Although not equivalent to cutaneous myeloid sarcoma (in which the skin infiltrate contains myeloblasts and/or promonocytes), this finding has been associated with poor outcomes in MDS.

Laboratory Features

Blood Counts

An important hallmark of MDS is ineffective hematopoiesis resulting in one or more peripheral blood cytopenias; the presence of at least one cytopenia is an absolute requirement for a diagnosis of MDS. The thresholds defining cytopenia for the purposes of establishing a diagnosis of MDS are shown in **Table 44-1**. Conversely, non-neoplastic causes of cytopenia (particularly anemia) are common, and only a very small minority of patients presenting with cytopenia actually have MDS.[19] Anemia is the most common presenting cytopenia in patients with MDS, and it is usually normocytic or macrocytic (median mean corpuscular volume of 97 fL). Less than 10% of patients with MDS have microcytic anemia, which in some cases represents acquired α-thalassemia.[20] There is frequently an increased red cell distribution width.[14,15] The anemia may be isolated, or it may co-exist with neutropenia and/or thrombocytopenia.[21] Adults with MDS present only rarely with isolated neutropenia or thrombocytopenia; however, this presentation is seen more frequently in pediatric MDS.[21-24] The cytopenias in MDS vary in severity, but they are typically sustained and progressive without treatment. Although reticulocyte production is typically low in MDS, the reticulocyte count may be spuriously elevated in some patients owing to abnormally retained cytoplasmic ribosomal material

(basophilic stippling) in circulating red blood cells rather than actual increased red blood cell production.[25,26] This may cause diagnostic confusion with hemolytic anemia.

Though documenting a persistent, unexplained cytopenia is a diagnostic requirement for MDS, blood counts may also play a role in excluding MDS in some instances. An important hallmark of MDS is ineffective hematopoiesis; an elevated blood count (cytosis) is unexpected and tends to exclude a diagnosis of MDS and, if a neoplastic process is confirmed, suggests a diagnosis of MDS/myeloproliferative neoplasm (MPN) or even "pure" MPN. With the exception of MDS cases with an inv(3)/t(3;3) cytogenetic abnormality or fulfilling features of **MDS with del(5q)**, a sustained platelet count of ≥450 × 10^9/L excludes a diagnosis of MDS, even if other cytopenias are present. A sustained elevated white blood cell count (≥13 × 10^9/L, not from lymphocytosis) or absolute and relative monocytosis (≥0.5 × 10^9/L and ≥10% of all leukocytes) also exclude a diagnosis of MDS and suggest an alternate diagnosis of MDS/MPN (**Table 44-1**). Finally, if ≥20% of circulating blasts are identified in the blood, even in a patient with leukopenia and <20% marrow blasts, the diagnosis is AML rather than MDS.

In summary, abnormal blood counts (cytopenia) are required to establish an initial diagnosis of MDS. Blood counts also establish the boundaries of MDS with MDS/MPN and AML. Within MDS, blood counts do not affect the current disease classification. However, blood counts play an important role in prognosticating MDS and when monitoring response to therapy (**Table 44-2**).

Microscopic Features in Peripheral Blood and Bone Marrow

Despite the presence of peripheral cytopenias, the marrow is typically hypercellular for age in MDS.[27] Less commonly, it is normocellular, and in 10% to 15% of cases, it is hypocellular for age (which defines a specific MDS subtype **MDS, hypoplastic** in the proposed 5th edition WHO classification). Hypocellularity is more frequent in pediatric MDS, after prior aplastic anemia, and in therapy-related MDS.[28-31]

The "dysplasia" in the disease name reflects an unusual set of abnormal cytologic features found in hematopoietic cells in the marrow and peripheral blood (**Table 44-3**; Figs. **44-1**–**44-3**). Although it is not pathognomonic for MDS, dysplastic morphology is a critical feature in establishing the diagnosis, and according to current International Consensus Classification (ICC) and proposed 5th edition WHO criteria, it must be present in at least 10% of cells to designate a lineage as dysplastic. At least one dysplastic lineage must be present to diagnose MDS, with rare exceptions for cases in which the diagnosis is established by increased blasts or specific genetic abnormalities in the absence of dysplasia. Some dysplastic features are best seen in mature cells in the peripheral blood, such as large or abnormally granulated platelets, basophilic stippling and poikilocytosis in red blood cells, and pseudo–Pelger-Huët anomaly and hypogranular cytoplasm in neutrophils. Others occur in immature precursors and are best seen in the bone marrow. Immature hematopoietic precursors (nucleated red blood cells, immature granulocytes, megakaryocyte nuclei, and mononuclear megakaryocytes) may circulate in the peripheral blood of patients with MDS and can show the same anomalies as seen in the marrow. However, nuclear irregularities in circulating erythroid cells are non-specific, as they can occur in non-MDS myeloid neoplasms and even

non-neoplastic conditions associated with leukoerythroblastosis. Marrow myeloblasts are increased in higher-grade MDS and may circulate in the peripheral blood, but they are always less than 20% of the bone marrow and peripheral blood nucleated cells. Auer rods are uncommonly seen in MDS; if present in blasts, they indicate highly aggressive disease, even if the actual blast percentages do not reach the designated thresholds.[32-34]

Table 44-1

Defining Cytopenias for Myelodysplastic Syndrome (MDS)

Peripheral Blood Count Abnormality	Threshold	Significance
Anemia	Hemoglobin <13 g/dL (men) or <12 g/dL (women)	Unexplained anemia is a cytopenia that can qualify for a diagnosis of MDS.
Neutropenia	Absolute neutrophil count (ANC) <1.8 × 10^9/L	Unexplained neutropenia is a cytopenia that can qualify for a diagnosis of MDS. Adjustment should be made for specific patient populations and according to the individual laboratory reference range.
Thrombocytopenia	Platelets <150 × 10^9/L	Unexplained thrombocytopenia is a cytopenia that can qualify for a diagnosis of MDS. Adjustment should be made according to the

Peripheral Blood Count Abnormality	Threshold	Significance
		individual laboratory reference range.
Monocytosis	Monocytes ≥0.5 × 10^9/L and comprising ≥10% of all leukocytes	Unexplained persistent monocytosis at the time of initial diagnosis disqualifies a diagnosis of MDS; CMML should be considered.
Leukocytosis	White blood count ≥13 × 10^9/L	Unexplained persistent leukocytosis (not from a lymphocytosis) at the time of initial diagnosis disqualifies a diagnosis of MDS; an MDS/MPN or MPN should be considered.
Thrombocytosis	Platelets ≥450 × 10^9/L	Unexplained persistent thrombocytosis at the time of initial diagnosis disqualifies a diagnosis of MDS; an MDS/MPN or

Peripheral Blood Count Abnormality	Threshold	Significance
		MPN should be considered. Exception: MDS diagnosis is allowed if criteria for MDS with del(5q) are present, or if there is inv(3) or t(3;3) cytogenetic abnormality involving *MECOM*.

Cell Lineage	Peripheral Blood	Bone Marrow
		s Large megakaryocytes with large hyperchromic nuclei

* Numerous types of abnormal forms may be seen, including ovalocytes, elliptocytes, teardrops, targets, and fragmented forms.

† In the normal marrow biopsy, CD34-positive myeloid blasts and other immature precursors are mostly located adjacent to bone trabeculae and blood vessels. In myelodysplastic syndrome, CD34-positive blasts may cluster and be abnormally located in the center of marrow spaces, hence the descriptive name “abnormal localization of immature precursors.”

Although experienced observers can generally agree on the presence of significant dysplasia and the presence or absence of increased blasts in a bone marrow sample,[35] the quantification of dysplastic features (i.e., involving one versus multiple lineages) is inherently variable among observers for several reasons: (1) the subtlety of some dysplastic features; (2) the observers’ experience; (3) differing significance and subjective weighting of individual dysplastic features; and (4) sampling variability in the cells observed on smears by different individuals.[36,37] It is important to emphasize that dysplastic features may be encountered in healthy individuals who do not have MDS and are even more frequently seen in patients with

secondary cytopenias caused by non-MDS conditions, as discussed in the Differential Diagnosis section of this chapter.[35,38-40]

In summary, with the exception of rare cases defined by specific cytogenetic abnormalities or mutations (discussed below), the presence of significant morphologic dysplasia of hematopoietic cells in the blood and/or bone marrow is required to diagnose MDS. Morphology also affects disease classification in terms of the blast percentage and presence of any Auer rods (ICC and 5th edition WHO classification), single versus multilineage dysplasia (ICC), marrow cellularity (5th edition WHO classification), ring sideroblasts (5th edition WHO classification), and bone marrow fibrosis (5th edition WHO classification). The only morphologic parameter incorporated into the International Prognostic Scoring System schemes (2012 revised version, IPSS-R and 2022 version incorporating mutations, IPSS-M) is the bone marrow blast percentage (**Table 44-2**). Bone marrow blast percentage is also important in monitoring MDS response after therapy.[41]

Flow Cytometry

MDS hematopoietic cells exhibit recurring quantitative and qualitative abnormalities in antigen expression and maturation patterns that can be interrogated by multiparameter flow cytometry immunophenotyping. These include abnormalities in the quantity and phenotype of blasts, the phenotype and light scatter qualities of maturing myeloid cells, the phenotype of erythroid cells and monocytes, and the maturation patterns of maturing myeloid cells and monocytes. A list of the main flow cytometry abnormalities observed in the most frequently assessed hematopoietic lineages (blasts, maturing myeloid cells, and monocytes) is shown in **Table**

44-4. These abnormalities correlate with the types and degrees of morphologic dysplasia and cytogenetic abnormalities, predict prognosis independent of other known risk factors,[42,43] have been shown to predict response to certain therapies (such as growth factors and hypomethylating agents),[44,45] and may provide insight into the biology and pathogenesis of MDS.[46] Although these phenotypic abnormalities have been validated in numerous studies, the way in which flow cytometry should be optimally applied to diagnose MDS remains controversial. Some of the abnormalities in myeloid and monocytic maturation patterns that are typical of MDS may also be seen in reactive conditions such as HIV infection, bone marrow regeneration, or autoimmune conditions.[47] Some aberrant antigen expression patterns have proved difficult to implement in a clinical laboratory setting.[48,49] In contrast, phenotypic aberrations observed in the blast compartment, such as a paucity of CD19-positive hematogones, altered expression of CD45, CD34, CD117, CD33, CD13, or CD38, and aberrant expression of lymphoid antigens (such as CD2, CD5, CD7, or CD56), appear to be more specific to MDS.[50,51]

Implementation of flow cytometry evaluation of MDS in individual laboratories requires sufficient case volume and experience. Ideally, published recommended panels should be used and multiple simultaneous abnormalities should be observed to suggest a diagnosis of MDS.[52,53] Updated guidelines put forth by the European LeukemiaNet/International Myelodysplastic Syndrome Flow Cytometry Working Group were published in 2023.[51] These guidelines recommend the use of flow cytometry, including a core set of 17 markers, to evaluate a bone marrow specimen taken for cytopenia and evaluation of the number and immunophenotype of myeloid precursor cells and maturing cell populations.[51] Overall, flow

cytometry immunophenotyping in suspected MDS is considered a helpful adjunctive test that can be used to support a diagnosis of MDS suspected on morphology and clinical features, particularly if the morphology is suboptimal or ambiguous.[54-56] Conversely, normal flow cytometry findings can prompt more careful investigations for non-MDS causes of cytopenia. However, flow cytometry findings alone should not be used to make a diagnosis of MDS if other criteria are lacking, nor should a negative flow cytometry result be used to unequivocally exclude the possibility of MDS. At the time of this writing, flow cytometry abnormalities do not affect prognostic schemes or MDS disease monitoring posttherapy.

Genetic Abnormalities

MDS is, by definition, a clonal disease, and one of the important hallmarks of abnormal MDS hematopoiesis is the presence of recurrent genetic abnormalities that originate in the MDS stem cell. These genetic abnormalities can be manifested as gross chromosomal alterations (detected by conventional karyotype or fluorescence in situ hybridization [FISH]), smaller chromosomal deletions or gains (detected by single nucleotide polymorphism [SNP] arrays or copy number abnormalities predicted by next-generation sequencing [NGS]), or mutations in specific genes. The recurring genetic abnormalities in MDS have several important implications: (1) they are often helpful in establishing a diagnosis; (2) certain specific abnormalities define particular disease subtypes within MDS; and (3) many recurring genetic abnormalities provide critical prognostic information, and some may suggest the use of specific targeted therapies.

Cytogenetic abnormalities are present at diagnosis in 50% to 60% of patients with MDS. The typical recurring clonal cytogenetic abnormalities seen in MDS are shown in **Table 44-5**.[57,58] The large majority of identified abnormalities consist of loss or gain of large segments of chromosomes, the most frequent being −7, del(5q), and +8. Deletions or losses of chromosomal material may also result from unbalanced translocations. It is presumed that these deletions or duplications result in the respective loss or gain of function of critical genes, but most of the genes in question are unknown. Balanced chromosomal translocations, which are common in AML, are infrequent in MDS. Many of the cytogenetic abnormalities in MDS appear to be secondary events that follow initial inciting somatic gene mutations, particularly the presence of complex karyotype in the setting of biallelic alteration of the *TP53* gene.[59-61]

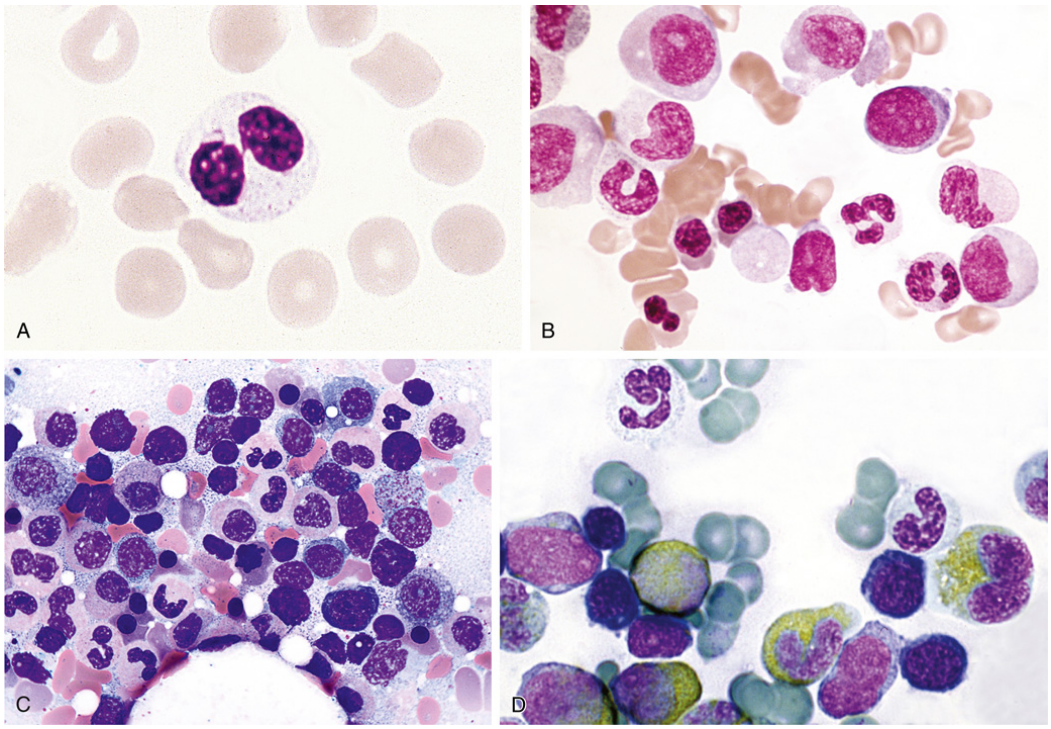

FIGURE 44-3 Granulocytic dysplasia in peripheral blood and bone marrow aspirate smears in myelodysplastic syndrome.A, Pseudo–Pelger-Huët cell with bilobed nucleus and hypogranular cytoplasm in peripheral blood smear. **B,** Asynchronous maturation of granulocytes with hyposegmented nuclei in bone marrow aspirate smear. **C,** Prominent granulocytic nuclear hyposegmentation and hypogranulation in bone marrow aspirate smear. **D,** Myeloperoxidase-negative granulocytes *(yellow is positive)* in bone marrow aspirate smear (myeloperoxidase stain, Giemsa counterstain).

Table 44-4

Abnormalities Identified by Flow Cytometry in Blast, Myeloid, and Monocytic Lineages in Myelodysplastic Syndrome

Cell Population	Abnormalities Seen in Myelodysplastic Syndrome
$CD34^+$ blasts	Increased numbers (≥3%) Decreased proportion of $CD19^+$ hematogones Altered CD45 and side scatter Increased $CD13^+/CD33^-$ or $CD13^-/CD33^+$ subset Increased CD11b expression Increased $CD123^+$ subset Decreased expression of CD38 or HLA-DR Aberrant expression of CD2, CD4, CD5, CD7, or CD56
Maturing myeloids	Decreased side scatter relative to lymphocytes Decreased expression of CD33 Increased expression of CD36, CD117, or HLA-DR Abnormal pattern of CD11b, CD13, CD16 expression Abnormal pattern of CD15 and CD10 expression

Cell Population	Abnormalities Seen in Myelodysplastic Syndrome
	Aberrant expression of CD34, CD5, CD56, or CD7
Monocytes	Decreased CD45/side scatter Decreased expression of CD13, CD15, CD36, CD64, CD11b, CD11c, HLA-DR, or CD14 Aberrant expression of CD56 (bright) or CD2

Whereas the effect of cytogenetics on MDS diagnosis and prognosis has been known for several decades, the significance of mutations in MDS has only become apparent in the last 10 to 15 years, facilitated by rapid advances in NGS technologies. Recurring somatic (i.e., acquired and residing in the MDS clone, not inherited in the germline) mutations in more than 100 genes have been identified and have fostered the development of NGS panels that cover most or all of these genes. Using such panels, at least one acquired genetic abnormality is found in over 90% of patients with MDS, a significantly higher proportion compared with abnormalities detected

by conventional karyotyping alone.[62-64] A list of the most commonly mutated genes in MDS is shown in **Table 44-6**. These genes fall into several general functional categories. Mutations affecting proteins in the *spliceosome complex,* which controls RNA splicing and thereby affects global gene expression, are among the most common in MDS. Spliceosome complex gene mutations in aggregate are found in more than 50% of MDS cases and tend to be mutually exclusive to one another.[65] Epigenetic regulation of gene expression is also commonly altered in MDS through mutations in genes controlling *DNA methylation* or *histone modification*. Other commonly mutated genes are those encoding hematopoietic *transcription factors, signaling proteins* (such as tyrosine kinases), *tumor suppressors* (typically DNA damage-response genes), and the *cohesin complex,* which controls the cohesion of sister chromatids, DNA repair, and transcriptional regulation.

Table 44-5

Common Recurrent Cytogenetic Abnormalities in Myelodysplastic Syndrome and Their Significance

Abnormality	Frequency in MDS	Significance
−7 or del(7q)	5%–10%	MDS defining in ICC Poor prognosis in CCSS
Del(5q)	15%	MDS defining in ICC Good prognosis in CCSS (if isolated)
+8	5%–10%	Intermediate prognosis in CCSS
+21	2%	Intermediate prognosis in CCSS
i(17q)	<1%	Intermediate prognosis in CCSS
−17, del(17p), unbalanced translocations at 17p	2%–5%	Indicate multihit/biallelic *TP53* lesion if accompanied by *TP53* mutation
t(3;3)(q21;q26), inv(3)(q21q26), and other	<1%	Considered AML-defining in ICC

Abnormality	Frequency in MDS	Significance
3q translocations involving *MECOM*		and WHO (≥10% blasts required in ICC). May have thrombocytosis Poor prognosis in CCSS
Complex karyotype (3 or more independent cytogenetic aberrations)	10%	MDS defining in ICC. Poor prognosis in ICC (very poor if >3 abnormalities)
Del(12p)	2%	Good prognosis in CCSS
Del(20q)	3%–5%	Good prognosis in CCSS (if isolated)
Del(11q)	2%	Very good prognosis in CCSS (if isolated)
–Y	5%	Can occur in older males without myeloid malignancy Very good prognosis in CCSS (if

Abnormality	Frequency in MDS	Significance
		isolated)

Several points must be made regarding the interpretation of NGS results in MDS.

1. The mutational landscape of MDS is complex and dynamic: an individual MDS case typically bears multiple mutations (e.g., in a spliceosome gene plus an epigenetic regulator), and in aggregate, MDS-associated mutations show nonrandom associations with one another. Moreover, some mutations may be present in only a subclone of the tumor cells, and the relative proportions of these subclones may shift during the course of the disease, with or without treatment.[66]
2. Mutations identical to those seen in MDS can occur in apparently healthy individuals without cytopenia (termed clonal hematopoiesis of indeterminate potential [CHIP]) or with unexplained cytopenia (termed clonal cytopenia of undetermined significance [CCUS]), neither of which is considered a hematologic neoplasm. Thus, the presence of MDS-associated mutations does not prove the presence of MDS.[67]
3. Even with the combination of conventional karyotype and broad NGS panels designed to pick up somatic mutations associated with MDS, 5% to 10% of bona fide MDS cases lack detectable genetic abnormalities.[62]
4. Some cases of MDS (with or without a family history of hematologic neoplasia) may bear inherited germline mutations in genes that predispose to the development of hematologic malignancy. Such potential germline mutations can be investigated by interrogating non-MDS patient tissue (cultured fibroblasts, hair follicles, or a skin biopsy) by NGS panels that are designed to detect these germline predisposition genes. Moreover, these germline mutations may be associated with dysplastic morphology and cytopenia

at baseline in patients with stable counts; thus, caution must be exercised when diagnosing MDS in a patient with a possible germline predisposition mutation.

Although the genes included in NGS panels vary, a list of 39 genes has been proposed to optimally include for mutation testing in adult patients with suspected MDS: *ASXL1, BCOR, BCORL1, CBL, CEBPA, CSF3R, DDX41, DMNT3A, ETV6, ETNK1, EZH2, FLT3, GATA2, GNB1, IDH1, IDH2, JAK2, KIT, KRAS, KMT2A, NF1, NPM1, NRAS, PHF6, PPM1D, PRPF8, PTPN11, RAD21, RUNX1, SETBP1, SF3B1, SRSF2, STAG2, TET2, TP53, U2AF1, UBA1, WT1,* and *ZRSR2*. This list includes mutations that are AML-defining (*NPM1* and *CEBPA*), that establish or exclude specific MDS subtypes *(SF3B1, RUNX1, TP53)*, and that influence prognosis or have therapeutic implications.[68]

According to the ICC, the presence of certain somatic genetic abnormalities (Tables **44-5** and **44-6**) is sufficient to confirm a diagnosis of MDS in a cytopenic patient, even if significant dysplasia is lacking. A del(5q) cytogenetic abnormality, when isolated or occurring with only one additional abnormality (except for −7 or del[7q]), is associated with a unique disease phenotype, response to a specific therapy, and a generally favorable prognosis (see section on **MDS with del[5q]**). The del(5q) typically occurs in primitive MDS stem cells as a founding event before the acquisition of other genetic aberrations and is associated with a highly differential gene expression profile.[69] Loss of chromosome 7 or del(7q) and complex karyotype (three or more independent cytogenetic abnormalities, seen more frequently in therapy-related MDS) are also considered to be MDS defining in patients with unexplained cytopenia. All other cytogenetic abnormalities are not considered sufficient to establish a

diagnosis of MDS in the absence of other diagnostic criteria. These include relatively common cytogenetic abnormalities associated with MDS (+8, del[20q], and –Y), which can also be seen in healthy older males (–Y) or in individuals with non-MDS causes of cytopenia, such as aplastic anemia or immune thrombocytopenia.[70-73] Some cytogenetic aberrations may be seen transiently in patients recovering from chemotherapy or receiving tyrosine kinase therapy, and their presence does not necessarily indicate emerging MDS in this setting.[74,75] Cytogenetic abnormalities in aplastic anemia, some of the congenital marrow failure syndromes, and megaloblastic anemia may be transient and recede spontaneously.[76-79] In rare pediatric patients with germline predisposition conditions (particularly germline *SAMD9/SAMD9L* and *SBDS* mutations) and an acquired –7, the cytogenetic abnormality may regress spontaneously to a normal karyotype, with no subsequent evidence of MDS or hematologic disease (so-called "somatic rescue").[80,81] Thus, though –7 is considered to be MDS-defining in the ICC, caution is advised in the context of some rare germline conditions.

Table 44-6

CMML, Chronic myelomonocytic leukemia; *ICC,* International Consensus Classification; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *NGS,* next-generation sequencing; *VAF,* variant allele frequency; *WHO,* World Health Organization Classification.

The MDS clonal precursor lesions CHIP and CCUS refer to the presence of mutated myeloid cells derived from a hematopoietic stem cell clone in individuals without any known hematologic neoplasm

and with normal blood counts (CHIP) or with an unexplained cytopenia (CCUS). CCUS is distinguished from MDS only by the presence of significant morphologic dysplasia; thus, a bone marrow biopsy to assess for dysplasia is mandatory to exclude MDS and diagnose CCUS. Given that all humans carry mutated hematopoietic stem cells (which progressively increase with age), a minimum threshold variant allele frequency (VAF) of 2% has been established in both the ICC and 5th edition WHO Classification to define CHIP and CCUS. The mutations seen in CHIP and CCUS affect genes that are frequently mutated in MDS and other myeloid neoplasms *(ASXL1, TP53, JAK2, SF3B1, TET2, DNMT3A)*. Compared with MDS, CHIP and CCUS tend to have a smaller number of detectable mutations (typically only a single mutation), and these mutations occur at a lower VAF.[82] However, given the overlap of the types of mutated genes and their VAFs between CCUS and MDS, the identification of MDS-type mutations alone, even in a patient with cytopenia, is not sufficient to establish a diagnosis of MDS in the absence of other diagnostic criteria. The only exceptions are mutations in *SF3B1* and multihit *TP53* lesions (with mutations at minimal VAFs of 10%), which are considered to be MDS-defining in a cytopenic patient in the ICC. Studies have revealed that some mutation patterns in CCUS indicate particularly high risk of progressing to MDS or another myeloid neoplasm; these include a mutant gene with a VAF ≥10%, the presence of a splicing gene mutation, a *TP53* mutation, or comutation of *TET2, ASXL1,* or *DNMT3A* with at least one other gene.[82,83] However, further study is needed to determine whether some CCUS cases can be considered equivalent to true MDS defined by morphologic dysplasia.[67]

It is well established that specific cytogenetic abnormalities strongly influence the prognosis of MDS, and thus the karyotype findings represent a cornerstone of MDS risk stratification schemes (**Table 44-7**). Not surprisingly, individual mutations also show a strong association with outcome in MDS, and the addition of mutational data enhances the ability of existing risk stratification schemes to predict prognosis in MDS.[59,84-87] Most of the recurring gene mutations in MDS have been associated with an unfavorable prognosis, whereas mutation in *SF3B1* is the only gene definitively associated with a more favorable prognosis (**Table 44-6**). Emerging data also suggest that *DDX41,* when occurring in the setting of a germline *DDX41* mutation, may also convey favorable prognosis, and MDS cases with mutated *DDX41* may not be effectively risk stratified by current prognostic schemes.[88]

Though several risk stratification schemes that incorporate mutation data have been developed,[59,84] the most comprehensive scheme is the IPSS-M, which incorporates mutations of 36 genes alongside the karyotype, blood counts, and bone marrow blast percentage.[85] It is interesting to note that the context of an individual gene mutation appears to modify its prognostic effect: for example, though *SF3B1* mutation is generally prognostically favorable, it imparts an unfavorable prognosis when it occurs in the setting of a del(5q) cytogenetic abnormality. In addition, evaluation of the *TP53* gene requires a more complex analysis: two lesions affecting the *TP53* gene (so-called “multihit” status or “biallelic inactivation”, typically a mutation in one allele in combination with an inactivating mutation or deletion of the other *TP53* allele) impart a dismal prognosis, but a single or monoallelic *TP53* mutation may not confer adverse prognosis in MDS.[89,90] *TP53* mutations in **MDS with del(5q)** (most

of which are monoallelic)[90] do predict a poorer response to lenalidomide.[91] It is important to note that bulk sequencing used in clinical practice does not resolve the genetic complexity of individual MDS cases, which could include subclones and low-level mutations not detectable by standard assays. Thus, it is likely that, in the future, more complex genetic analyses (such as single-cell sequencing) may achieve more accuracy in predicting the prognosis of patients with MDS.[92,93]

Table 44-7

Comprehensive Cytogenetic Scoring System for MDS

Prognostic Subgroup	Cytogenetic Abnormalities	Median Overall Survival*
Very good	–Y, del(11q)	5.4 years
Good	Normal, del(5q), del(12p), del(20q), double including del(5q)	4.8 years
Intermediate	del(7q), +8, +19, i(17q), any other single or double independent clones	2.7 years
Poor	–7, inv(3)/t(3q)/del(3q), double including –7/del(7q), complex (3 abnormalities)	1.5 years
Very poor	Complex (>3 abnormalities)	0.7 years

Aberrant Function of Hematopoietic Cells

A variety of losses of function (or abnormal function) have been described in the hematopoietic cells of patients with MDS. Neutrophil precursors may lose myeloperoxidase function in rare MDS cases, and in the large subset of MDS cases with ring sideroblasts, there is abnormal accumulation of iron in the mitochondria of erythroid precursors. Small paroxysmal nocturnal hemoglobinuria clones,[94,95] reticulocytosis simulating a hemolytic process,[25,26] increased hemoglobin F,[96] changes in blood group antigen expression,[97] and acquired α-thalassemia[98,99] can occur in association with MDS and may cause diagnostic confusion with non-MDS conditions (see this chapter's discussion of Differential Diagnosis).

Diagnosis

There is no single completely sensitive or specific feature or test that can be used to unequivocally diagnose MDS; because of these limitations and the numerous clinical situations that can mimic MDS, clinicopathologic correlation and integration of information from the multiple diagnostic modalities are essential for an accurate and reliable diagnosis. The minimal diagnostic criteria for MDS are listed in **Box 44-1**. The application of these criteria must take into account the clinical context of each case because many of these abnormalities may be present in non-MDS conditions. Cytopenias should be stable or worsen over several weeks at least; thus, it is of value to seek blood counts prior to those of the bone marrow date to document chronicity. If a subsequent marrow sample is performed at a later time, any dysplastic changes should persist or worsen. If only unilineage dysplasia is present without excess blasts and no cytogenetic or molecular abnormalities are detected, it is reasonable

to request the patient be followed, and another marrow sample should be taken at a later date to document persistent dysplasia and cytopenia before MDS is diagnosed outright.[100]

To evaluate a potential case of MDS, the minimal requisite studies are (1) a complete blood count with white blood cell differential and examination of the peripheral smear, (2) a Wright-Giemsa–stained bone marrow aspirate smear, (3) a hematoxylin-eosin–stained biopsy section, (4) an iron stain on a bone marrow aspirate smear to evaluate for ring sideroblasts, (5) a full bone marrow karyotype, and (6) NGS studies to include evaluation of at least *SF3B1* and *TP53* genes. Flow cytometry to identify immunophenotypic aberrancies may be a helpful adjunctive test to support a diagnosis of MDS, although it is not part of the formal diagnostic criteria. Review of a high-quality aspirate smear is paramount, both to accurately identify dysplasia and to establish an accurate blast count. The aspirate should optimally contain spicules with well-preserved, well-stained cellular trails that allow counting of at least 500 cells. If an aspirate is unobtainable because of fibrosis, a touch imprint from the bone marrow core often provides adequate material for evaluation. The bone marrow biopsy is essential to evaluate the cellularity, topography of maturing myeloid and erythroid elements and megakaryocytes, and focal accumulations of blasts that may not be represented in the aspirate smear. The bone marrow biopsy also evaluates for other pathologies that may mimic MDS, such as metastatic carcinoma or lymphoma involving the bone marrow. A reticulin stain should be performed on the biopsy to assess for fibrosis, which is relevant for diagnosis of **MDS with increased blasts and fibrosis** subtype in the proposed 5th edition WHO classification. Reticulin stain is also an independent prognostic factor in MDS.[101]

Though cytogenetic abnormalities in a putative new MDS case should always be evaluated on a conventional karyotype of bone marrow, FISH analysis for the common MDS abnormalities (particularly loss of chromosomes 5 and 7) may be helpful if the karyotype fails or is insufficient (less than 20 metaphases).[102] However, FISH probably does not add meaningful information in the workup of a possible MDS case if 20 normal metaphases are obtained from a bone marrow sample.[103,104] The iron stain should be performed on a bone marrow aspirate smear rather than on the biopsy specimen because decalcification leaches iron from the biopsy sample; in some instances, ring sideroblasts may be identifiable in a nondecalcified paraffin-embedded particle section stained for iron. An immunostain for CD34 in the biopsy section can help corroborate the aspirate blast count and may upgrade the diagnosis if the CD34-positive cells in the core biopsy are greater than the blast count in the aspirate smear (discussed in the section on **MDS-EB**).[105,106] Immunostaining of the biopsy section with a megakaryocyte marker such as CD61 or CD42b helps reveal small, dysplastic megakaryocytes that can be missed on routine histology. Clinical tests are important in excluding metabolic abnormalities that can cause cytopenias mimicking MDS, including vitamin B_{12}, folate, pyridoxine, and copper deficiencies. Paroxysmal nocturnal hemoglobinuria clones detected by flow cytometry, platelet function abnormalities on coagulation testing, and other acquired functional abnormalities in hematopoietic cells may be seen both in MDS and in non-neoplastic conditions and are not generally used in the diagnosis of MDS.

Classification

Disease Border: Myelodysplastic Syndrome Versus Clonal Hematopoiesis

MDS is a clonal disease that is separated from other clonal hematopoietic proliferations by the presence of significant morphologic dysplasia in at least one lineage or persistent and unexplained increase in bone marrow blasts (below the level required to define AML). The minimal diagnostic criteria for MDS are shown in **Box 44-1**, and features of non-MDS clonal hematopoietic proliferations are shown in **Table 44-8**. In evaluating dysplasia in a cytopenic patient, it is critical to consider non-neoplastic causes of dysplasia and cytopenia (discussed in the Differential Diagnosis section). Some data suggests that the distinction between CCUS with high-risk mutations and lower-risk MDS is irrelevant, as these patients may have a similar prognosis.[83] However, until further data is accumulated, the requirement for identifying morphologic dysplasia to diagnose MDS has been retained in both the ICC and proposed 5th edition WHO classification; the only exceptions that are made are for a small group of genetic aberrations that are considered to be MDS-defining in the ICC (Tables **44-5** and **44-6**).

Box 44-1 Minimal Criteria for a Diagnosis of Myelodysplastic Syndrome (ICC)

AML, Acute myeloid leukemia; *VAF,* variant allele frequency.

- Sustained unexplained anemia, neutropenia, or thrombocytopenia in the absence of a sustained unexplained leukocytosis or absolute and relative monocytosis (see **Table 44-1** for requisite levels)

AND

- At least one of the following:
  - Dysplastic morphology in erythroid cells, granulocytes, or megakaryocytes, affecting at least 10% of the cells of at least one of these lineages.
  - Increased blasts in bond marrow (at least 5% of marrow cells) or blood (at least 2% of leukocytes) not attributable to exogenous growth factor administration or transient marrow recovery from injury, and in the absence of diagnostic criteria for AML established by ≥20% blood/marrow blasts and/or an AML-defining genetic abnormality
  - Del(5q), −7, del(7q), or complex karyotype detected on bone marrow cytogenetics
  - *SF3B1* mutation at VAF of ≥10%
  - Multihit TP53 mutation defined by a somatic *TP53* mutation at VAF ≥50%
  - Multihit TP53 mutation defined by a somatic *TP53* mutation at VAF of ≥10% and with inactivation of the second *TP53* allele through mutation (VAF of ≥10%), deletion, or copy-neutral loss-of-heterozygosity

Table 44-8

MDS, Myelodysplastic syndrome; *VEXAS,* vacuoles, E1-enzyme, X-linked, autoinflammatory, somatic.

* Defined as identification of a pathogenic somatic mutation in hematopoietic cells (from blood or bone marrow) in a gene recurrently mutated in myeloid neoplasms, at VAF ≥2%, or a clonal cytogenetic abnormality detected by karyotype.

† Requires bone marrow examination.

‡ Del(5q), −7, del(7q), or complex karyotype detected on bone marrow conventional karyotype, or multihit *TP53* mutation (VAF ≥10%) or *SF3B1* mutation (VAF ≥10%).

Disease Border: Myelodysplastic Syndrome Versus Acute Myeloid Leukemia

An AML-defining threshold of 30% was used in the prior French-American-British (FAB) classification of AML. In this scheme, MDS with 20% to 30% marrow blasts was designated refractory anemia with excess blasts in transformation (RAEB-T).[32] In the 2001 WHO classification, the threshold for separating MDS and AML was decreased to 20%, and the diagnostic category of RAEB-T was thus eliminated and merged into AML. This change generated some discussion and disagreement in the literature[107,108] centered on the ambiguity of distinguishing MDS from AML on the basis of the single parameter of the blast percentage.[109,110] Moreover, in clinical practice, the most biologically relevant distinction is often not the separation of MDS from AML but the separation of de novo AML from MDS and MDS-related AML entities (such as AML progressed

from MDS in the ICC, AML with myelodysplasia-related changes [AML-MRC] in the 4th edition WHO classification, and AML, myelodysplasia-related [AML-MR] in the proposed 5th edition WHO classification). The therapeutic approach to MDS with excess blasts is frequently similar to that of AML that has progressed from MDS. In contrast, intensive chemotherapy may induce long-term complete remissions in patients with de novo AML, particularly those with certain specific recurring genetic abnormalities (AML-RGA). Younger patient age and a more rapid clinical presentation without prior cytopenia are clues to de novo AML-RGA rather than MDS-related disease.[111] The AML-RGA cytogenetic aberrations *PML*::*RARA*, *RUNX1*::*RUNX1T1*, and *CBFB*::*MYH11* have been considered to be AML-defining irrespective of the blast count. In the ICC and proposed 5th edition WHO classification, this list of AML-RGA entities has been expanded to include several other genetic aberrations that are now considered to be AML defining, even in cases with <20% blasts, as data suggest that the blast count is not relevant in the presence of these genetic lesions (see **Chapter 46**).[112-116] In the ICC, a minimum threshold of 10% blasts is applied for any AML diagnosis based on an AML-defining genetic feature. These changes result in some cases previously categorized as MDS with excess blasts-2 (MDS-EB2) in the revised 4th edition WHO classification to be considered as AML and potentially eligible for AML-type intensive chemotherapy. It should be emphasized that such cases are rare; the vast majority of myeloid neoplasms bearing AML-defining genetic aberrations present with a blast percentage of at least 20%.

MDS is a bone marrow failure syndrome characterized by ineffective hematopoiesis, whereas AML is a dysregulated hyperproliferation of blasts. In this context, some cases with a blast

percentage of 20% to 30% (i.e., prior RAEB-T) may behave like MDS, with clinical manifestation as marrow failure and cytopenias, whereas others behave like AML, with rapid accumulation of blasts in the blood and bone marrow. It is often not possible to reliably distinguish between a progressive blast hyperproliferation and a more stable marrow failure syndrome on the basis of a single bone marrow examination, but serial examination may allow this distinction (**Fig. 44-4**); if the marrow blast percentage remains relatively constant or rises slowly over time to exceed the 20% threshold, the case may continue to behave like MDS, whereas if the blast percentage rises abruptly, the disease process has likely transformed to a proliferative state and may be best considered AML. Overall, de novo AML cases with low blast counts (20% to 29%) that lack AML-RGA abnormalities appear to behave more indolently and generally lack hyperproliferative features, similar to high-grade MDS, an observation that underscores the arbitrary nature of the 20% blast cutoff that has been used to define AML.[117] Conversely, some patients with 10% to 19% blasts may benefit from treatment with more intensive AML-like regimens versus standard MDS-directed therapies.[112,118,119]

In light of these evolving concepts surrounding the MDS versus AML distinction (and increased overlap between AML-directed and MDS-directed therapies), the ICC introduced a category of disease intermediate between MDS and AML to acknowledge the biological continuum between these two myeloid neoplasms. This new disease category, **MDS/AML**, encompasses cases of cytopenic patients exhibiting morphologic features of MDS with 10% to 19% blasts in blood or bone marrow, thus corresponding to most cases of MDS-EB2 in the revised 4th edition WHO classification and **MDS with**

increased blasts-2 (MDS-IB2) in the proposed 5th edition WHO classification. This change allows patients with **MDS/AML** to be potentially eligible for both MDS and AML trials and treatments while accumulating data to optimize the treatment approach to such patients. Rather than basing treatment decisions on an arbitrary blast threshold cutoff, this more nuanced approach takes into account features such as stable versus rapid progression in blast count and cytopenias and the mutation profile, potentially driving more patient-centered therapeutic choices.[118,119] Trials are needed to investigate the effectiveness of novel AML and MDS therapies as applied to this "transitional" MDS/AML group.[120]

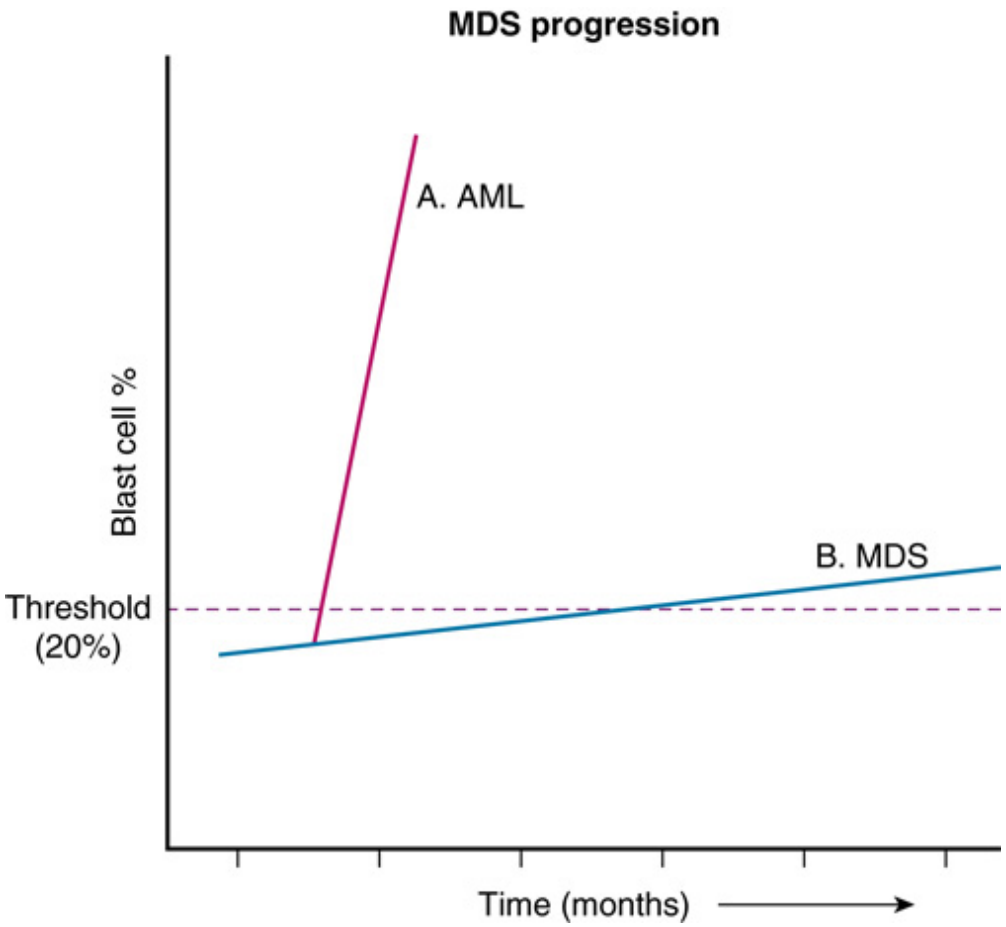

FIGURE 44-4 Blast progression over time in myelodysplastic syndrome (MDS). If the blast percentage in marrow rises rapidly *(line A)*, the case may be more biologically related to acute myeloid leukemia (AML), even at earlier blast percentages of <20%. In contrast, if the blast percentage rises slowly over several months *(line B)*, the case is likely more biologically akin to MDS, even if the blast percentage exceeds 20%.[109] Despite these differences in disease tempo that suggest different clinical behaviors, MDS and AML

continue to be separated largely by a static blast threshold of 20%.

Disease Heterogeneity Within Myelodysplastic Syndrome

The biological behavior of MDS is highly variable, ranging from genetically and clinically stable disease to aggressive disease that acquires increasingly complex genetic abnormalities and rapidly progresses to severe marrow failure and cytopenias or AML.[60,61,121] Some subtypes of MDS are associated with a relatively long median survival (6–8 years or longer), a low rate of progression to AML (<10% overall), and a low percentage of blasts in the peripheral blood (<2%) and bone marrow (<5%).[13,32] These lower-risk subtypes include **MDS with del(5q)**, **MDS with mutated *SF3B1***, and **MDS, not otherwise specified (MDS-NOS)**.

More aggressive cases of MDS are often characterized by an increase in blasts; a blast threshold of 5% in the bone marrow or 2% in the blood or the presence of Auer rods in blasts defines the MDS subtype **MDS-EB**. *TP53* mutation in MDS also defines a highly aggressive disease with several unique features and defines a new entity: **MDS with mutated *TP53*.** The distinction between aggressive subtypes of MDS and AML is often less critical than the distinction between aggressive MDS and lower-risk MDS subtypes for the purpose of determining the general direction of treatment; for these reasons, the ICC introduced the transitional disease category of **MDS/AML**, as discussed above. It should be emphasized that, although different MDS disease categories are associated with different clinical outcomes, risk assessment in MDS for the purpose of

clinical management is best assessed by applying the IPSS-M or IPSS-R.

International Consensus Classification and World Health Organization Classification

In 1976, the FAB Working Group proposed that the previously chaotic nomenclature of MDS be standardized and created a classification that was subsequently updated in 1982.[32,109,122] The FAB classification of MDS included five categories: refractory anemia (RA), RA with ring sideroblasts (RARS), RA with excess blasts (RAEB), RAEB in transformation (RAEB-T), and chronic myelomonocytic leukemia (CMML). This classification standardized the reporting of data related to these diseases and allowed the comparison of treatment regimens in defined sets of patients. Subsequent revisions of this classification were incorporated in the 3rd edition of the WHO classification published in 2001 and were retained with relatively minor modifications in the 4th edition of this classification published in 2008. A revised 4th edition of the WHO classification of MDS was issued in 2016 and published in 2017.[123] This update included nomenclature changes enacted to avoid reference to specific cytopenias (such as anemia) in the disease names and included most cases of the prior entity “acute erythroid leukemia, erythroid/myeloid subtype” into MDS-EB by calculating the bone marrow myeloblast percentage from all nucleated cells, irrespective of the percentage of erythroid cells. In 2022, two separate updated classifications of MDS were introduced: the ICC and the 5th edition WHO classification.[124-126] Though the ICC has been published in its final form,[124] the 5th edition WHO classification Blue Book is still pending publication at the time of this writing. This chapter focuses

on the ICC scheme, providing information regarding the 5th edition WHO classification approach based on the published proposal[125] with the caveat that there may be differences in the final published 5th edition Blue Book. A comparison of the ICC, revised 4th edition WHO classification, and proposed 5th edition WHO classification is shown in **Table 44-9**.

Myelodysplastic Syndrome With del(5q) (MDS-del5q)

MDS with del(5q) (MDS-del5q) is a discrete subset of MDS with an excellent prognosis.[127-130] In the proposed WHO 5th edition classification, this entity is named **myelodysplastic neoplasm with low blasts and isolated 5q deletion (MDS-5q)**. MDS-del5q also corresponds to the WHO revised 4th edition classification's **myelodysplastic syndrome with isolated del(5q)**. The only updates to this entity from the revised 4th edition classification are to allow cases with pancytopenia or 1% peripheral blood blasts (measured on only one occasion) in MDS-del5q; previously, these rare cases were placed into the MDS, unclassifiable category, which has been eliminated in the ICC.

Unlike the majority of MDS, **MDS-del5q** has a female predominance. Patients typically present with macrocytic anemia with megaloblastoid erythropoiesis, normal granulopoiesis and neutrophil count, and normal or increased platelets associated with increased and prominently mononuclear bone marrow megakaryocytes. Ring sideroblasts and/or *SF3B1* mutation may be present and should not lead to misclassification as another MDS subtype if isolated del(5q) is present on karyotype; it is interesting that, in the context of a del(5q) cytogenetic abnormality, *SF3B1* mutation has an adverse prognostic effect.[85] Granulocytic dysplasia is

usually minimal or absent, and there must be no excess of blasts in blood or bone marrow.[131,132] MDS-del5q has a favorable prognosis, whether del(5q) is the sole finding on karyotype or if one (but not two or more) additional cytogenetic abnormality is present.[133,134] Thus, one other cytogenetic abnormality (aside from monosomy 7 or del[7q]) is allowed in **MDS-del5q.** Defined as such, survival in **MDS-del5q** is excellent, with a low rate of progression to higher-grade MDS or AML. It should be noted that patients usually have excellent response to the thalidomide analog lenalidomide, and thus this MDS subtype has therapeutic implications.[123,135,136] However, as with other lower-grade MDS subtypes, a small number of cases behave more aggressively and may progress to AML. In particular, *TP53* mutation is present in up to 20% of cases and is associated with increased risk of leukemic progression and poorer lenalidomide response.[91] The *TP53* mutation may be identified by sequencing or by p53 immunohistochemistry and is usually monoallelic.[90,91] According to the ICC, a multihit *TP53* abnormality excludes a diagnosis of **MDS-del5q**. The diagnostic criteria for **MDS-del5q** are shown in **Table 44-10**.

Table 44-9

Myelodysplastic Syndromes in Adults (Aged ≥18 Years, Blasts <20%): International Consensus Classification and Comparison to Revised 4th Edition and Proposed 5th Edition WHO Classifications (Adult Patients)

International Consensus Classification	Revised 4th Edition WHO Classification	Proposed 5th Edition WHO Classification
MDS with mutated *SF3B1* (MDS-*SF3B1*)	**MDS with ring sideroblasts with single lineage or multilineage dysplasia** (MDS-RS-SLD, MDS-RS-MLD) (most cases)	**MDS with low blasts and *SF3B1* mutation** (MDS-*SF3B1*)
MDS with del(5q)	**MDS with isolated del(5q)**	**MDS with low blasts and isolated 5q deletion (MDS-5q)**
MDS with mutated *TP53* (MDS-TP53)	**None** (distributed across several MDS subtypes)	**MDS with biallelic *TP53* inactivation** (MDS-bi*TP53*)

International Consensus Classification	**Revised 4th Edition WHO Classification**	**Proposed 5th Edition WHO Classification**
MDS/AML with mutated *TP53* (MDS/AML-*TP53*)	**MDS with excess blasts-2** (MDS-EB2)	**MDS with biallelic *TP53* inactivation** (MDS-bi*TP53*)
MDS-NOS, without dysplasia	**MDS, unclassifiable**	**Clonal cytopenia of undetermined significance** (CCUS)
MDS-NOS, with single lineage dysplasia (MDS-NOS-SLD)	**MDS with single lineage dysplasia** (MDS-SLD, most cases)	**MDS with low blasts** (MDS-LB), some *SF3B1* wild-type **MDS-LB with ring sideroblasts,** and some **MDS, hypoplastic** (MDS-h)
MDS-NOS with multilineage dysplasia (MDS-NOS-MLD)	**MDS with multilineage dysplasia** (MDS-MLD, most cases)	**MDS with low blasts** (MDS-LB) **most *SF3B1* wild-type MDS-LB with ring**

International Consensus Classification	Revised 4th Edition WHO Classification	Proposed 5th Edition WHO Classification
		sideroblasts, and some MDS, hypoplastic (MDS-h)
MDS with excess blasts (MDS-EB)	**MDS with excess blasts-1** (MDS-EB1)	**MDS with increased blasts-1** (MDS-IB1) **and some MDS with increased blasts and fibrosis** (MDS-f)
MDS/AML*	**MDS with excess blasts-2** (MDS-EB2)	**MDS with increased blasts-2** (MDS-IB2) and some **MDS with increased blasts and fibrosis** (MDS-f)

AML, Acute myeloid leukemia; *MDS,* myelodysplastic syndrome; *NOS,* not otherwise specified; *WHO,* World Health Organization.

* MDS/AML cases (excluding MDS/AML-*TP53*) are further subdivided into MDS/AML with MDS-related gene mutations,

MDS/AML with MDS-related cytogenetic abnormalities, and MDS/AML-NOS.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of Myeloid Neoplasms and Acute Leukemia: integrating morphological, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228. Khoury JD, Solary E, Abla O, et al, The 5th edition of the World Health Organization classification of haematolymphoid tumours: myeloid and histiocytic/dendritic neoplasms. *Leukemia*. 2022;36(7):1703-1719.

Myelodysplastic Syndrome With Mutated *SF3B1* (MDS-*SF3B1*)

In the proposed WHO 5th edition classification, this entity corresponds to **myelodysplastic neoplasm with low blasts and *SF3B1* mutation (MDS-LB-*SF3B1*).** It includes most, but not all cases previously classified as **myelodysplastic syndrome with ring sideroblasts (MDS-RS)** in the WHO revised 4th edition classification. The presence of ring sideroblasts in all myeloid neoplasms is closely associated with mutation in the spliceosome gene *SF3B1,* which conveys a favorable prognosis.[102] In most MDS cases bearing an *SF3B1* mutation, ring sideroblasts are frequent and account for at least 15% of the erythroid cells; in a significant minority, they are present but account for less than 15% of all erythroid cells. Only 1% to 2% of MDS cases with *SF3B1* mutation lack ring sideroblasts altogether.[137-139] Unsupervised molecular clustering data have shown that *SF3B1* mutation segregates a major MDS subgroup with a large number of differentially expressed genes.[140,141]

In addition, *SF3B1* mutation, rather than the morphologic finding of ring sideroblasts, appears to define a more homogeneous MDS disease entity with respect to favorable patient outcome; MDS cases with ring sideroblasts that lack *SF3B1* mutation have less favorable prognosis, a different mutation profile, and more frequent multilineage dysplasia.[138,142,143] For these reasons, the revised 4th edition classification entity MDS-RS has been replaced in the ICC by **MDS with mutated *SF3B1* (MDS-*SF3B1*),** and ring sideroblasts no longer affect the classification of MDS in the ICC (except to signify a type of erythroid dysplasia). Though **MDS-*SF3B1*** is not subdivided based on single versus multilineage dysplasia, the presence of excess blood (≥2%) or bone marrow (≥5%) blasts or Auer rods excludes the diagnosis and mandates classification as **MDS-EB**. **MDS-*SF3B1*** frequently has a bimodal red cell distribution in the peripheral blood, with a normocytic or microcytic, hypochromic population and a macrocytic population.[32] The diagnostic criteria for **MDS-*SF3B1*** are shown in **Table 44-11**.

Table 44-10

Myelodysplastic Syndrome, Not Otherwise Specified (MDS-NOS)

The ICC entity **MDS-NOS** corresponds to the proposed WHO 5th edition classification entity **myelodysplastic neoplasm with low blasts (MDS-LB)** and encompasses most cases categorized as **myelodysplastic syndrome with single lineage dysplasia**

(MDS-SLD), myelodysplastic syndrome with multilineage dysplasia (MDS-MLD), and myelodysplastic syndrome, unclassifiable (MDS-U) in the revised 4th edition WHO classification.

Table 44-11

BM, Bone marrow; *MDS,* myelodysplastic syndrome; *NA,* not applicable; *PB,* peripheral blood; *VAF,* variant allele frequency; *WHO,* World Health Organization.

MDS-NOS includes lower-grade MDS cases that fail to place in the two genetically defined subtypes of **MDS-del5q** or **MDS-*SF3B1*.** Like the revised 4th edition WHO classification, these cases continue to be separated into entities with significant (at least 10%) dysplasia in only one lineage (single lineage dysplasia, **MDS-NOS-SLD**) and those with significant dysplasia involving two or three hematopoietic lineages (multilineage dysplasia, **MDS-NOS-MLD**). It should be noted that the dysplastic lineages often do not coincide with the cytopenic lineage or lineages.[135,136] That being said, most cases of **MDS-NOS-SLD** present with anemia and isolated erythroid lineage dysplasia. Pancytopenia was exclusionary for **MDS-SLD** in the revised 4th edition WHO classification category and mandated categorization as **MDS-U** in an MDS with single lineage dysplasia because of apparently more aggressive behavior.[135,144] In the ICC, pancytopenia is no longer taken into account in MDS classification, as the degree of cytopenias is already taken into account in current MDS prognostic schemes. Though distinction between single and multilineage dysplasia is not perfectly reproducible among pathologists[145] (and has been eliminated as a requirement in **MDS-**

LB in the proposed 5th edition WHO classification), it has been retained in the ICC because several studies have shown it to delineate prognostically distinct disease categories. **MDS-NOS-SLD** has an indolent clinical course with a median survival of 5.5 to 6 years, leukemic progression of less than 5%, and survival approaching that of age-matched peers in some series, reflecting a relatively stable disease process.[13,24,121,127,128] Because dysplasia in only one lineage may be borderline and relies on subjective observation, it is reasonable to defer an initial diagnosis of **MDS-NOS-SLD** to ensure cytopenia and dysplasia persist upon follow-up with repeat bone marrow biopsy. Indeed, most data suggest there is no detriment to delaying treatment in lower-grade MDS subtypes such as **MDS-NOS-SLD**.[146,147]

The prognosis of **MDS-NOS-MLD** is substantially worse than that of **MDS-NOS-SLD**, justifying the continued requirement to distinguish these entities.[121,127-129,144,148-150] The median survival of **MDS-NOS-MLD** (as defined in the prior WHO classifications) has been reported to be 2.5 to 3 years and 10% to 11% overall progression to AML[121,127,128]; however, this may change given the creation of the genetic categories **MDS-*SF3B1*** and **MDS-*TP53*,** which alters the makeup of the ICC entity **MDS-NOS-MLD**. Cytogenetic abnormalities are present in approximately 50% of patients with **MDS-NOS** and tend to be more frequent in **MDS-NOS-MLD** than in **MDS-NOS-SLD**, but there are no specific or defining cytogenetic abnormalities.[121,151]

MDS-NOS, without dysplasia encompasses cases previously categorized as **MDS-U** in the revised 4th edition WHO classification because of unexplained cytopenias and MDS-defining cytogenetic abnormalities, but it lacks sufficient dysplasia in any lineage (or

increased blasts) to qualify for a morphologic diagnosis of MDS. These cases are very rare; indeed, the failure to identify dysplasia may reflect an inadequate or suboptimal bone marrow sample rather than true absence of dysplasia. As the list of defining genetic abnormalities in the ICC is now different from those defining **MDS-U** in the revised 4th edition WHO classification, the frequency, clinical features, and prognosis of these cases remain to be determined. The proposed 5th edition WHO classification does not allow a diagnosis of MDS without morphologic dysplasia or increased blasts and encompasses **MDS-NOS, without dysplasia** within CCUS. One study has validated the neoplastic nature of MDS-defining cytogenetic abnormalities in cytopenic patients, as they have similar outcomes whether MDS-defining dysplasia is present or absent.[152] The diagnostic criteria for the three **MDS-NOS** subtypes are shown in **Table 44-12**.

Myelodysplastic Syndrome With Mutated *TP53* (MDS-*TP53*)

MDS with mutated *TP53* (MDS-*TP53*) represents a new genetically-defined MDS entity with highly aggressive clinical behavior. It corresponds to **myelodysplastic neoplasm with biallelic *TP53* inactivation (MDS-bi*TP53*)** in the proposed 5th edition WHO classification. Unlike other MDS cases, blast percentage does not appear to influence prognosis in the setting of a *TP53* mutation,[90,153] even when including cases with sufficient blasts to warrant a diagnosis of AML. Thus, in the ICC, **MDS-*TP53*** is considered within the disease group of *TP53*-mutated myeloid neoplasms together with **MDS/AML with mutated *TP53*** and **AML with mutated *TP53*** (including pure erythroid leukemia).[153,154] In one series of *TP53*-mutated MDS, about half of the cases lacked excess blasts, and the vast majority of these showed

multilineage dysplasia.[155] *TP53* mutation can be suspected in MDS based on intense nuclear staining of at least 2% of cells in the bone marrow trephine biopsy,[156,157] although these results should be confirmed by mutation testing. Because cases appear to behave similarly irrespective of the blast count, **MDS-*TP53*** is not subdivided based on the blood and bone marrow blast thresholds of 2% and 5%, respectively. Instead, it encompasses MDS cases with any blast percentage up to 9% in the marrow or blood, with or without Auer rods.

As *TP53* functions as a tumor suppressor gene, both copies of the gene must be inactivated to fully realize the loss of its tumor suppressor function. Supporting this concept, studies have shown that the highly aggressive phenotype conferred by mutated *TP53* in MDS requires multiple hits to the *TP53* gene ("multihit" or "biallelic" status). Multihit *TP53* status in MDS can be confirmed by the presence of two or more distinct *TP53* mutations (each at VAF ≥10%) or a single *TP53* mutation (VAF ≥10%) associated with either deletion involving the *TP53* locus at 17p13.1 or copy-neutral loss of heterozygosity (LOH) at the 17p *TP53* locus; a single *TP53* mutation with VAF ≥50% is also considered to represent presumptive evidence of multihit status caused by loss of the wild-type *TP53* allele.[90,154,158] In the absence of LOH information, the presence of a single *TP53* mutation at VAF ≥10% in the context of any complex karyotype is also considered equivalent to a multihit *TP53* in the ICC, although this is not considered sufficient to confirm biallelic *TP53* according to the proposed 5th edition WHO classification.[90,154] This is based on evidence that multihit *TP53* is strongly associated with complex karyotype, whereas a true monoallelic *TP53* mutation usually displays a noncomplex karyotype; the VAF may be lower than expected as a

result of hemodilution or other preanalytic factors.[90] At the time of this writing, any mutation in the *TP53* gene is considered pathogenic, but it remains to be determined whether different mutations convey different disease phenotypes and if these should be incorporated into risk stratification of *TP53*-mutated cases.[155,159] It is emphasized that complex karyotype alone without a *TP53* mutation (even if there is deletion of the *TP53* locus at 17p) does not qualify for this category, as these cases have a better prognosis than cases of *TP53*-mutated MDS.[153,160] Monoallelic *TP53* mutations in MDS differ biologically from those of multihit *TP53* cases, and they are not included in the **MDS-*TP53*** category. The diagnostic criteria for **MDS-*TP53*** are shown in **Table 44-13**.

Table 44-12

Myelodysplastic Syndrome With Excess Blasts (MDS-EB)

MDS-EB corresponds to **myelodysplastic neoplasm with increased blasts [MDS-IB1]**, in the proposed WHO 5th edition and **myelodysplastic syndrome with excess blasts-1 (MDS-EB1)** in the revised 4th edition WHO classification. **MDS-EB** can exhibit any degree of morphologic dysplasia and variable cytogenetic abnormalities, but it manifests excess (≥5%) blasts in the bone marrow. Less commonly, blasts may be <5% in the marrow but

increased (≥2%) in the blood, or Auer rods may be present in blasts; such cases should also be categorized as MDS-EB, irrespective of the bone marrow blast count.[32,161,162] CD34 immunostaining of the biopsy section helps reveal increased blasts in cases with a hemodilute or poorly stained aspirate smear (particularly in cases with increased bone marrow fibrosis) and may be useful all MDS cases, even if the aspirate is of high quality. If blasts enumerated from a CD34 immunostain appear to account for at least 5% of the core biopsy cells, it is reasonable to upgrade a case to **MDS-EB** even if the aspirate blast count is <5%.[106,163] CD117 also stains blasts in most MDS cases, but interpretation is more difficult, as this marker also stains early erythroids, promyelocytes, and mast cells, rendering myeloblast enumeration challenging; in general, CD117 staining on myeloblasts is stronger than on early erythroids but weaker than on mast cells. Median survival is approximately 16 months for **MDS-EB**, and approximately 25% of patients progress to AML. Some cases of **MDS-EB** harbor an *SF3B1* mutation, and this mutation does not appear to convey a favorable prognosis in this context as it does for lower-grade MDS subtypes.[142]

Table 44-13

BM, Bone marrow; *LOH,* loss of heterozygosity; *MDS,* myelodysplastic syndrome; *NA,* not applicable; *PB,* peripheral blood; *VAF,* variant allele frequency.

Cases with exactly 1% circulating blasts appear to exhibit aggressive behavior similar to those of **MDS-EB**[164,165]; such cases were considered within **MDS-U** in the revised 4th edition WHO classification. Though it was noted in that prior classification that 1%

circulating blasts should be documented on two separate occasions, this may be difficult to do in practice; moreover, a blast percentage of exactly 1% is not likely to be reproducible on multiple measurements. For these reasons, both the ICC and WHO have applied a 2% peripheral blood blast threshold for **MDS-EB**, and 1% blood blasts measured on a single occasion is acceptable for lower-grade MDS entities. However, the ICC recommends that these patients be followed closely and be classified as **MDS-EB** if blood blasts at the level of 1% or higher are documented on multiple occasions, even if marrow blasts remain at <5%. The diagnostic features of **MDS-EB** are shown in **Table 44-14**.

Table 44-14

AML, Acute myeloid leukemia; *BM,* bone marrow; *MDS,* myelodysplastic syndrome; *NA,* not applicable; *PB,* peripheral blood; *VAF,* variant allele frequency; *WHO,* World Health Organization Classification.

Myelodysplastic Syndrome/Acute Myeloid Leukemia (MDS/AML)

To acknowledge the biological continuum between MDS and AML and some imprecision in counting blasts around the historic 20% threshold, myeloid neoplasms with 10% to 19% blasts in the blood and/or marrow are placed in a new disease entity, **MDS/AML,** in the ICC. The optimal treatment of this group of patients (previously classified as **MDS-EB2** in the revised 4th edition WHO classification and still classified as **myelodysplastic neoplasm with increased blasts-2 [MDS-IB2]** in the proposed 5th edition WHO

classification) is still unknown; the future personalized treatment of individual patients in this **MDS/AML** group will likely be dictated by genetic, biological, and patient-related factors rather than an arbitrary blast cutoff.[119,154,166] Studies have shown that mutations in some genes (*NRAS, PTPN11, FLT3, CBL, IDH1,* and *IDH2*) could drive the progression of MDS to AML and thus inform the management of patients with MDS/AML.[167,168] Stable versus rapid progression of the blast percentage and cytopenias during clinical follow-up may also be informative (**Fig. 44-4**).[169] In the meantime, this change allows patients with **MDS/AML** to be eligible for both MDS and AML trials, providing them more treatment options. Pediatric patients with 10% to 19% blasts (with the exception of those with AML-defining genetic aberrations) continue to be classified as **MDS-EB**, as these patients have features that are distinct from adult **MDS/AML**. AML-defining cytogenetic aberrations or mutations (*NPM1* or in-frame bZIP *CEBPA*) must be excluded in patients presenting with ≥10% bone marrow or blood blasts.

It is recommended that patients with MDS/AML who are treated as AML be subclassified according to the genetic AML categories **MDS/AML with MDS-related cytogenetic abnormalities**, **MDS/AML with MDS-related gene mutations**, **MDS/AML with mutated *TP53***, and **MDS/AML, NOS**[170] (see **Chapter 46**). It should be noted that, unlike **MDS with mutated *TP53,*** which requires multihit *TP53* mutation, a monoallelic *TP53* mutation suffices to classify an **MDS/AML** case with 10% to 19% blasts as **MDS/AML with mutated *TP53***. This is based on evidence that, in cases with increased blasts (≥10%), there appears to be no significant difference in prognosis conveyed by monoallelic versus multihit

TP53.[154] The diagnostic features of **MDS/AML** are shown in **Table 44-15**.

Myelodysplastic Syndrome in Children and Refractory Cytopenia of Childhood

MDS is rare in children (<18 years of age), and the disease subtypes and spectrum of mutations differ from those found in adults.[171-174] **MDS-SF3B1** is exceedingly rare in children, and if ring sideroblasts are observed in a pediatric patient, Pearson's syndrome must be excluded.[175] **MDS-del5q** is also very rare in children. When a del(5q) is present, other karyotypic abnormalities are usually present, often in the context of a complex karyotype and therapy-related disease.[176] **Refractory cytopenia of childhood (RCC)** represents cytopenic conditions affecting children that have diagnostic features largely similar to those seen in cases of **MDS-NOS** with hypocellular bone marrow. **RCC** has a lower incidence of somatic mutations and cytogenetic abnormalities than adult MDS, and it more frequently occurs in the setting of a genetic predisposition syndrome (see the separate section in this chapter, Ontogenetic Qualifier to Myelodysplastic Syndrome: Germline Predisposition).[22,177,178] Aside from **RCC** and myeloid leukemia associated with Down syndrome, other MDS cases occurring in children are classified like adult MDS, with the following exceptions: (1) There is no distinction between **MDS-NOS-SLD** and **MDS-NOS-MLD** in pediatric populations, as this is still of uncertain prognostic significance.[179] (2) The ICC entity **MDS/AML** does not apply to pediatric MDS, as pediatric patients with MDS with increased blasts (even those with 20%–30% blasts) may not require intensive induction therapy, but rather are often treated with up-front

stem cell transplant. In pediatric patients (<18 years of age), **MDS-EB** extends to up to 19% of bone marrow or blood blasts.[178]

The proposed 5th edition WHO classification eliminates **RCC** and replaces it with *childhood MDS with low blasts,* including hypoplastic cases. This entity corresponds to most cases fulfilling features of **RCC;** however, it is important to note that a subset of **RCC** cases may not be true myeloid neoplasms and thus are not equivalent to bona fide MDS (**Table 44-16**).[180] As with adult MDS, it is critically important to exclude non-neoplastic mimickers. Because of the frequent hypocellularity in pediatric MDS, distinction from aplastic anemia may be particularly challenging. Although application of the diagnostic criteria of **RCC** usually allows accurate distinction,[28,181] extended observation may be required in some cases to distinguish hypocellular **RCC** cases from aplastic anemia. An important consideration in **RCC** and other MDS cases occurring in pediatric patients is their frequent occurrence on the background of a genetic predisposition syndrome (up to 30% of cases, which may increase in the future as more genes predisposing to myeloid malignancies are discovered).[178] Thus, screening for a germline syndrome should be performed in any pediatric patient presenting with RCC or other MDS.

The International Consensus Classification (ICC) of hematologic neoplasms with germline predisposition, pediatric myelodysplastic syndrome, and juvenile myelomonocytic leukemia. *Virchows Arch*. 2023;482(1):113-130.

Ontogenetic Qualifier to Myelodysplastic Syndrome: Therapy-Relatedness

In the 4th edition and prior WHO classifications, therapy-related MDS was grouped together with therapy-related AML, as these diseases were felt to have similarly poor prognoses, irrespective of the blast count.[182] Therapy-related MDS occurs principally after exposure to agents that cause damage to DNA (alkylating agents, platinum derivatives, nitrosoureas) or after exposure of the bone marrow to ionizing radiation.[183] The mechanism by which these agents cause disease appears to be through cytotoxic effects on the marrow environment that foster the expansion of preexisting hematopoietic stem cell clones bearing mutations, typically in DNA-damage response genes such as *TP53* and *PPM1D*.[184,185] The onset of

clinical disease may begin as early as 6 months or 1 year after initiation of therapy with the causative agent; more characteristically, latency is 2 years or more and peaks at 5 to 6 years. Patients typically present with cytopenias and morphologic dysplasia similar to non–therapy-related disease, but the marrow is more often hypocellular than in non–therapy-related disease. More than 90% of therapy-related MDS cases show an abnormal karyotype. Cytogenetic abnormalities involving deletions of chromosomes 5 and 7 are relatively common.[186]

Although as a whole therapy-related MDS tends to show more rapid progression of cytopenias, progression to AML, and shorter survival compared with de novo disease, data suggest that this is caused by overrepresentation of high-risk genetic lesions (such as *TP53* and complex karyotypes) compared with de novo MDS.[187-189] For example, the IPSS-R scheme effectively risk stratifies patients with therapy-related MDS, and the minority of these patients who have low IPSS-R risk scores appear to have a more favorable prognosis.[189] For these reasons, therapy-relatedness is no longer used as a major MDS disease classifier in the ICC. Instead, it is applied as a qualifier to the MDS disease subtype, which is classified the same as for de novo disease (example: **MDS with mutated *TP53*, therapy-related**, or **MDS-NOS-MLD, therapy-related**). As it is sometimes unclear whether an MDS developing in a patient with cytotoxic exposure is truly related to the prior therapy or is merely coincidental, the proposed 5th edition WHO classification prefers the term “post cytotoxic therapy” in lieu of “therapy-related” to designate such cases.

Ontogenetic Qualifier to Myelodysplastic Syndrome: Germline Predisposition

As mentioned previously, MDS in children frequently occurs in the background of a congenital syndrome. Congenital syndromes associated with pediatric MDS include Fanconi anemia, Down syndrome, severe congenital neutropenia (Kostmann syndrome), Shwachman-Diamond syndrome, dyskeratosis congenita, amegakaryocytic thrombocytopenia, Bloom syndrome, GATA2 deficiency, and others.[190-192] The ICC categorizes germline predisposition states into three categories: (1) germline predisposition without a constitutional disorder affecting multiple organ systems (which typically have no prodromal phenotype prior to the development of MDS or another myeloid neoplasm); (2) germline predisposition associated with a constitutional platelet disorder (such as germline *RUNX1, ANKRD26,* or *ETV6* mutation); and (3) germline predisposition associated with a constitutional disorder affecting multiple organ systems (such as Fanconi anemia, neurofibromatosis, or dyskeratosis congenita).[178]

MDS evolving from a congenital syndrome often behaves differently from de novo disease. For example, the incidence of MDS and AML in Down syndrome is increased, but the clinical behavior and underlying biology of MDS in young patients (<5 years of age) with Down syndrome differ markedly from MDS in other clinical settings: somatic *GATA1* mutations are common, and these patients have a very favorable prognosis. Such cases are considered within a single category of "myeloid leukemia associated with Down syndrome," irrespective of the blast percentage.[193-196] Patients with Fanconi anemia may be particularly sensitive to preparative regimens for allogeneic transplantation.

It is essential in diagnosing pediatric MDS to note whether the MDS is primary or secondary to such an antecedent condition

because this may affect treatment decisions and alter outcome. MDS occurring in the background of a familial condition could also influence the choice of family members as donors if stem cell transplantation (SCT) is being considered as a therapeutic option. It is also important to note that some adults presenting with MDS have predisposing constitutional gene mutations that convey increased risk of myeloid malignant neoplasms and are probably under recognized in clinical practice; germline *DDX41* mutation is the most common of these and does not have a prodromal phenotype prior to presentation with MDS or AML.[88] Thus, in any patient with MDS, it is important to query carefully to uncover any personal or family history of cytopenias that may be a clue to the presence of an underlying predisposing syndrome, which should stimulate testing using NGS panels targeting the common germline predisposition genes (which overlap only partly with genes that are also somatically mutated in MDS).[197,198] As the germline mutation may be newly acquired in the patient without any family history, more widespread germline testing in older patients and in those without a family history may be warranted.[178]

Prognostic Scoring Systems

In an attempt to improve the ability to predict disease course in individual patients, the International MDS Study Group, composed of clinical experts in the treatment of MDS, developed the IPSS for MDS in 1997.[151] The original proposal, which used a limited number of prognostic variables (marrow blast percentage, three tiers of karyotype abnormalities, and the number of cytopenias), was refined as the IPSS-R in 2012.[199] The IPSS-R was more complex than the IPSS, using a larger number of blast strata, five instead of three

categories of karyotype findings, and more detailed assessments of cytopenias in each lineage. This combined information generates five IPSS-R risk groups instead of the previous three risk IPSS groups. An alternative WHO classification–based prognostic scoring system (WPSS) uses karyotype risk, WHO disease subtype, and transfusion requirement to identify five prognostically distinct risk groups.[147]

The IPSS-R has been widely adopted in clinical practice as a basis for treatment decisions and appears to predict outcome both at diagnosis and dynamically in patients being observed at later time points.[200,201] By incorporating the bone marrow blast percentage, the IPSS-R scheme overlaps somewhat with the ICC and WHO classifications. However, the IPSS-R does not incorporate ring sideroblasts, peripheral blood blasts, Auer rods, the number of dysplastic lineages, bone marrow cellularity, or bone marrow fibrosis, which are used as classifiers in the ICC and the proposed 5th edition of the WHO classification.

The IPSS-M was published as an update to the IPSS-R scheme.[85] The IPSS-M differs from the IPSS-R as follows: (1) Neutropenia (absolute neutrophil count $<0.8 \times 10^9$/L) is no longer taken into account, as it was not found to be prognostic when additional genetic information was incorporated. (2) Anemia and thrombocytopenia are incorporated as continuous variables rather than categories with specific cutoff values. (3) Mutations in 36 genes with variable contributions of the prognostic score have been incorporated. (4) Allowance is made for missing values, with a range of uncertainty for the calculated prognostic score. The IPSS-M output is a number score, with 0 representing the median survival of all patients in the cohort and each increase or decrease of 1 representing a doubling or halving of the hazard ratio, respectively, for leukemia-free survival.

Based on the score ranges, there are six prognostic categories, ranging from Very Low to Very High. Most MDS patients fall into the lower risk cohorts, but a subset of patients have very high risk, some with a hazard ratio of over 4 compared to the median survival of MDS patients. Compared to the IPSS-R, the IPSS-M more accurately predicts MDS outcome.[85] The IPSS-M risk calculator can be accessed at **https://www.mds-risk-model.com**.

Additional Considerations in Myelodysplastic Syndrome Diagnosis

Hypoplastic Myelodysplastic Syndrome

Most cases of MDS have hypercellular marrow despite the presence of cytopenias, reflecting the ineffective hematopoiesis that is a hallmark of the disease. However, 10% to 15% of MDS in adults (and a much higher percentage in children) has reduced marrow cellularity for age.[31,202,203] The clinical behavior of these hypoplastic MDS cases tends to reflect the blast percentage, similar to other MDS subtypes. Some studies suggest that hypocellularity in MDS is an independent favorable prognostic variable.[204,205] Because aplastic anemia may manifest mildly dysplastic morphology and even transient clonal cytogenetic abnormalities similar to MDS, distinction between hypoplastic MDS and aplastic anemia, which is a destruction of hematopoietic stem cells usually caused by an autoimmune process, may be difficult (see this chapter's section on Differential Diagnosis).[30,76-78] Hypoplastic MDS is more likely than more cellular MDS to respond favorably to immunosuppression, suggesting a possible etiologic link to aplastic anemia.[206-210] Additionally, the finding of a hypocellular marrow in a younger patient with MDS

raises consideration of a genetic predisposition syndrome, and such patients may not benefit from immunosuppressive therapy.[211]

Hypoplastic MDS is not a specific disease subtype in the 4th edition WHO classification or ICC, but it has been added as a specific low-risk MDS subtype in the proposed 5th edition WHO classification. To accurately diagnose this entity, is it important to have an adequate bone marrow biopsy in a newly diagnosed MDS case so that cellularity can be accurately estimated, and the bone marrow cellularity should be specified in the bone marrow report. In patients <70 years of age, hypocellularity is defined as cellularity of <30%; for patients ≥70 years of age, it is defined as cellularity <20%.[206] It is important to note that some cases of AML and MDS with excess blasts may present with a hypocellular marrow, and these cases are not included within this hypoplastic MDS entity. Thus, a careful blast count on the (often paucicellular) aspirate smear must be performed to distinguish hypoplastic **MDS-EB** from **hypoplastic MDS** as defined in the 5th edition WHO classification; CD34 staining of the biopsy section can be helpful in this regard.[30]

Myelodysplastic Syndrome With Fibrosis

Mild-to-moderate and occasionally marked reticulin fibrosis can occur in MDS.[101,212,213] Significant fibrosis (grade 2 or 3 of 3 in the WHO myelofibrosis grading scheme) confers an inferior prognosis to MDS that is independent of the karyotype risk, WHO disease subtype, or IPSS-R score.[101] Classification of MDS cases with fibrosis is based on the same criteria used in other MDS cases, and MDS with fibrosis is not a specific MDS disease subtype in the revised 4th edition WHO classification or the ICC. The proposed 5th edition WHO classification has introduced a new subtype of MDS with increased blasts and

increased fibrosis, termed **MDS with increased blasts and fibrosis.** It is important to note that MDS cases that lack increased blasts may also show increased fibrosis, and such cases have a poorer prognosis than their counterparts lacking increased fibrosis: the 5th edition WHO entity **MDS with increased blasts and fibrosis** is specifically limited to cases with increased blood or bone marrow blasts and excludes cases with biallelic *TP53* mutation or any AML-defining genetic abnormalities.[125]

Fibrosis may complicate the diagnosis by interfering with the acquisition of an aspirate (so-called "dry tap"). Thus, quantitation of blasts on smears and by flow cytometry may be significantly hampered and requires careful analysis of the core biopsy sample to estimate the blast count. Immunohistochemical staining with CD34 to highlight possible increased blasts in the bone marrow biopsy sample is essential in fibrotic cases with a compromised aspirate smear. CD61 immunostaining is also helpful to reveal micromegakaryocytes that are commonly seen in fibrotic MDS cases. Wright-Giemsa–stained touch imprints from the bone marrow core should always be made if the bone marrow aspirate is dry or appears aspicular, as accurate blast counts can usually be obtained from well-prepared touch preparations. Fibrotic MDS cases may mimic primary myelofibrosis, other chronic MPNs with fibrosis, and acute megakaryoblastic leukemia. These differential diagnoses are discussed later in this chapter.

Erythroid-Predominant Myelodysplastic Syndromes

Cases of MDS with erythroid predominance (≥50% erythroid elements) accounts for about 15% of all MDS cases and have a higher incidence of high-risk cytogenetic abnormalities than other MDS;

they are also more frequently therapy related.[214] Erythroid predominance does not define a specific MDS subtype; cases are most frequently classified as MDS-NOS-MLD, MDS-NOS-SLD, or MDS-*SF3B1*.[214] It is critical to distinguish erythroid-predominant MDS, in which erythroid elements are increased and dysplastic but exhibit complete maturation, from pure erythroid leukemia, a subtype of acute myeloid leukemia in which erythroid maturation is arrested and there is a proliferation of primitive erythroblasts. Pure erythroid leukemia is a highly aggressive AML subtype with very short survival and nearly universal highly complex karyotypes and multihit *TP53* mutation.[215-218] Some cases of **MDS with mutated *TP53*** are erythroid-rich and may have increased pronormoblasts, yet do not meet criteria for pure erythroid leukemia because of insufficient erythroid elements (<80%) or insufficient pronormoblasts (<30%).[219] Prior studies have suggested that increased pronormoblasts represents an unfavorable prognostic feature in MDS in general.[220] However, enumeration of pronormoblasts in MDS is not part of current classification schemes, in part because pronormoblast numbers and erythroid left shift may be influenced by metabolic deficiencies, treatment, and effects of exogenous growth factors.[221]

Differential Diagnosis

One of the most challenging aspects of MDS diagnosis confronting both the clinician and the pathologist is its differential diagnosis with non-neoplastic and other neoplastic conditions that may cause cytopenia. Dysplasia—the main and defining morphologic finding of MDS—can be seen in many non-neoplastic cytopenic conditions and

in several non-MDS myeloid neoplasms.[40] Navigating this minefield of potential MDS mimickers requires consideration of all available diagnostic information and an open mind in approaching a putative MDS diagnosis. Specific scenarios of differential diagnosis with MDS are presented herein.

Non-Neoplastic Conditions Associated With Morphologic Dysplasia and Cytopenia

Megaloblastic Anemia

Megaloblastic anemia often exhibits dysplastic features in the erythroid lineage that closely mimic MDS. Therefore, it is essential that this readily treatable, non-neoplastic condition be excluded during the diagnostic evaluation for possible MDS. In megaloblastic anemia, overt megaloblastic changes usually predominate over dysplastic features, and conversely, the megaloblastoid changes in MDS are usually milder than those seen in megaloblastic anemia. Megaloblastic changes in the myeloid series (giant band forms and metamyelocytes) are rare in MDS but commonly accompany the prominent erythroid changes of megaloblastic anemia. The differential diagnosis may be complicated by the rare occurrence of transient clonal cytogenetic abnormalities, such as del(7q), in megaloblastic anemias.[79] When the differential diagnosis of a case includes megaloblastic anemia, serum vitamin B_{12} and folate levels should be measured before a diagnosis of MDS is rendered. Measurement of methylmalonic acid levels is a more sensitive indicator of vitamin B_{12} deficiency and may be helpful in borderline cases.

Chemotherapy-Induced Dysplasia and Cytopenias

Many chemotherapy agents induce dysplastic and megaloblastoid morphology and cause peripheral blood cytopenias. This combination may mimic MDS, or even occasionally AML, if neutropenic patients receive granulocyte-colony stimulating factor that transiently increases the blast percentage in bone marrow or blood. The most striking megaloblastic changes are seen with folate antagonists (e.g., methotrexate) and drugs that directly interfere with DNA synthesis (e.g., antimetabolites such as hydroxyurea and 5-fluorouracil). Early recovery from chemotherapy may be manifested as a transient burst of regenerating blasts potentially mimicking MDS with excess blasts.

The type of response to specific chemotherapeutic agents varies among individuals, in part on the basis of polymorphisms of cellular defense genes and drug transport proteins such as MDR1. At least partially for these reasons, in some patients, even standard doses of chemotherapy may lead to prolonged cytopenias, marrow hypocellularity, and morphologic changes mimicking MDS.[222-224] Distinguishing prolonged chemotherapy effects from emerging therapy-related MDS may be difficult or impossible by the examination of a single bone marrow sample; identification of MDS-associated immunophenotypic abnormalities detected by flow cytometry may be helpful in this regard.[225] Cytogenetics may be helpful if MDS-associated clonal abnormalities such as −7 or del(5q) are demonstrated, but mutations found on NGS are less specific, as they can represent clonal hematopoiesis after chemotherapy that may not progress to bona fide MDS.[226] Often, one must resort to clinical follow-up, monitoring of peripheral blood counts, and if necessary, repeated marrow examination to resolve this differential diagnosis. Of particular note in this context, up to 2% of patients with acute promyelocytic leukemia treated with combined all-trans retinoic acid

(ATRA)/anthracycline regimens develop therapy-related MDS or AML, with typical dysplastic morphology and MDS-type cytogenetic abnormalities and lacking the *PML*::*RARA* abnormality of the original leukemia.[227]

Post-Acute Myeloid Leukemia Dysplasia and Clonal Hematopoiesis

After chemotherapy for AML, marrow hematopoiesis may show dysplastic morphology and/or clonal genetic abnormalities, even if the bone marrow blast percentage is less than 5% and the platelet and neutrophil counts have recovered sufficiently to qualify for complete remission. Clonal cytogenetic abnormalities and gene mutations present in the original AML, particularly *DNMT3A, TET2,* and *ASXL1* (so-called "DTA" mutations), may persist as a chemotherapy-resistant preleukemic stem cell population.[228,229] If morphologic dysplasia and cytopenias persist and bone marrow blasts are ≥5%, this is considered to represent residual AML,[170] although biologically, the disease may be more related to MDS-EB.[230] In the post-AML treatment setting, dysplastic changes and even clonal genetic abnormalities should be interpreted with caution and described in the report, but not used in isolation to confirm recurrent or residual AML in the absence of increased blasts. Measurable residual AML is detected by flow cytometry and/or sensitive genetic studies that assess for certain AML-specific genetic aberrations: *NPM1* mutation or *PML*::*RARA*, *RUNX1*::*RUNX1T1*, *KMT2A*::*MLLT3*, *DEK*::*NUP214*, *BCR*::*ABL1*, or *CBFB*::*MYH11* rearrangements.[170]

Marrow Recovery After Acute Marrow Injury or Stem Cell Transplantation

After an acute marrow injury (such as an injury induced by chemotherapy, toxin, infection, or occasionally an unknown cause), there may be a transient excess of blasts in blood or marrow accompanying marrow recovery, along with dysplastic changes, especially in the erythroid and occasionally megakaryocytic lineages. Identification of left-shifted myeloid forms and toxic granulation in the blood can be helpful clues to appropriate marrow recovery rather than MDS with circulating blasts; circulating granulocytic forms in MDS are often hypogranulated but only seldom show toxic granulation. Similar changes may be seen at the time of donor marrow engraftment after myeloablative SCT. Macrocytosis and mild megaloblastoid change are also often seen after SCT and may persist for months or years. This phenomenon can complicate the morphologic interpretation of post-SCT bone marrow samples, and megaloblastic changes should not be overinterpreted as evidence of new or persistent MDS in this context. Molecular chimerism studies that assess donor engraftment will usually resolve the interpretation of these morphologic findings. However, rare cases of donor-derived MDS or AML may occur after SCT,[231] particularly in patients with germline predisposition syndromes who receive SCT from a similarly affected sibling.[232] Therapy-related MDS can also occur after autologous stem cell transplant as a result of prior chemotherapy or radiotherapy for the patient's primary malignant disease or preparative regimens for the SCT.[233-235]

Marrow Dysplasia in HIV Infection

Patients with HIV/AIDS may develop peripheral blood cytopenias. Marrow examination in such cases often reveals dysplastic morphologic features, particularly in the erythroid and

megakaryocytic lineages, potentially mimicking MDS. Despite such dysplastic morphology, cytogenetic abnormalities of MDS are lacking in cytopenic HIV-infected patients. The cause of the dysplastic morphology in these patients is not always clear. Some antiviral agents used in treating HIV infection may contribute to the cytopenias and the dysplastic morphologic abnormalities, but similar features were observed in patients with HIV/AIDS before the advent of effective therapy for the disease.

Congenital Dyserythropoietic Anemias

MDS may mimic congenital dyserythropoietic anemias (CDAs) by exhibiting internuclear bridging, megaloblastoid hematopoiesis, and multinucleation of erythroid progenitors as manifestations of erythroid lineage dysplasia.[236] This differential diagnosis is critical because the treatment and prognosis of MDS and CDAs differ drastically. Of great practical help is the fact that MDS is a relatively common disease, whereas CDAs are very rare. CDA types I and II typically present in childhood or adolescence, but even in infancy and childhood, MDS predominates in incidence over CDAs and must be assiduously ruled out before CDA is diagnosed. In older patients, this caveat is even more important because CDA becomes progressively less frequent with advancing age. In CDAs, dysplastic morphology and cytopenias are restricted to the erythroid lineage. If neutropenia, thrombocytopenia, or dysplasia in the granulocytic or megakaryocytic lineages is present, a diagnosis of MDS should be strongly considered. Cytogenetics and sequential clinical observation may be helpful, as progressive disease over time is more suggestive of MDS.

Non-Myelodysplastic Syndrome Sideroblastic Anemias

By far, the most frequent cause of ring sideroblasts in bone marrow is MDS, but other diverse conditions are also associated with ring sideroblasts. Active alcohol abuse inhibits multiple steps of heme synthesis, resulting in the accumulation of mitochondrial iron as ring sideroblasts. Dietary deficiencies associated with alcoholism may result in concomitant megaloblastoid hematopoiesis, and acute alcohol intoxication may cause vacuolization of erythroid precursors, changes shared with MDS.[237,238] Other reversible causes of ring sideroblasts include antituberculosis drugs (especially isoniazid),[239] severe copper deficiency or zinc poisoning,[240,241] and penicillamine therapy.[242]

Congenital causes of sideroblastic anemia are diverse, including X-linked (the most common), autosomal, and mitochondrial inheritance forms.[243,244] In contrast to the typically macrocytic anemia of MDS, anemia in the congenital sideroblastic cases is microcytic and hypochromic and may respond to exogenous pyridoxine; patients may have accompanying iron overload. Pearson's syndrome is a mitochondrial cytopathy characterized by refractory sideroblastic anemia, vacuolated marrow erythroid precursors, and exocrine pancreatic dysfunction. Pearson's syndrome has a mitochondrial inheritance pattern and an onset of disease symptoms in infancy. Variant mitochondrial cytopathies with ring sideroblasts have also been described, and ring sideroblasts may also be seen with erythropoietic protoporphyria. All of these congenital diseases are rare, and in most cases, the cytopenia and morphologic abnormalities are restricted to the erythroid lineage.

Copper Deficiency and Zinc Toxicity

Copper (and selenium) deficiency and zinc toxicity, which itself causes copper deficiency,[241] can present with pancytopenia and dysplastic marrow morphology, closely mimicking MDS.[245] Vacuolization of erythroid precursors may be prominent, in addition to vacuolated granulocyte precursors and neutropenia. Patients are often premature infants; those with prolonged parenteral hyperalimentation, postgastrectomy, or malnourished states; or those undergoing copper chelation therapy.[246] Hematopoietic parameters may improve with folate and vitamin B_{12} treatment, but this does not prevent progression of the neurologic abnormalities. Accurate diagnosis and early treatment are essential to prevent irreversible neurologic damage and to avoid erroneous treatment for misdiagnosed MDS.

Arsenic Exposure

Arsenic trioxide, now frequently used to treat acute promyelocytic leukemia and under investigation for use in other disorders, causes striking dysplastic morphology in marrow, particularly in erythroid progenitors, mimicking the erythroid dysplasia of MDS.[247]

Chronic Viral Infections

Epstein-Barr virus, herpesvirus, and cytomegalovirus infections may present with hypercellular marrow and dysplastic marrow morphology.[248,249] Chronic parvovirus B19 infection can also mimic MDS if the giant pronormoblasts are interpreted as dysplastic cells. Some cases of MDS may present with pure red cell aplasia, and thus both MDS and parvovirus infection must be considered in the differential diagnosis of this condition.[250,251] Morphologic

abnormalities in parvovirus infection are usually restricted to the erythroid lineage.

Aplastic Anemia

Aplastic anemia may have dysplastic morphology in hematopoietic progenitors and occasionally has cytogenetic abnormalities similar to those of MDS.[29,31,77,78] The interrelationship of MDS and aplastic anemia is complicated and not completely understood. Some cases of aplastic anemia progress to MDS, and conversely, some cases of MDS have hypocellular marrow; thus, distinction between hypocellular MDS and aplastic anemia may be difficult. Somatic mutations occur in approximately one-third of patients with aplastic anemia, and these genes include those frequently mutated in MDS, such as *BCOR/BCORL, DNMT3A,* and *ASXL1*.[252] In MDS, the dysplastic features tend to be more prominent than in aplastic anemia, and the cytopenias are disproportionate to degree of hypocellularity. Persistent clonal cytogenetic abnormalities strongly favor MDS. In some cases, it is not possible to discriminate unequivocally between hypocellular MDS and aplastic anemia, except with clinical follow-up. CD34 immunostaining can be useful in distinguishing MDS from aplastic anemia because CD34 cells are never increased in aplastic anemia, whereas they are increased in a substantial subset of hypocellular MDS.[30] Clonal proliferations of cells with loss of glycosylphosphatidylinositol (GPI)–anchored proteins (characteristic of paroxysmal nocturnal hemoglobinuria [PNH]) may be seen in both MDS and aplastic anemia, although the PNH clone size is usually larger in aplastic anemia than in MDS.

Paroxysmal Nocturnal Hemoglobinuria

PNH is a clonal cytopenic condition associated with a somatic mutation in in the *PIGA* gene (phosphatidylinositol glycan anchor biosynthesis, class A), which is responsible for the first step in the synthesis of the GPI anchor that attaches a subset of proteins to the cell surface. PNH, aplastic anemia, and MDS are interrelated entities. A subset of patients with MDS has marrow hypocellularity (see the section, Hypoplastic Myelodysplastic Syndrome), similar to aplastic anemia and PNH,[31] and a subset of patients with PNH progresses to MDS (up to 5%) or AML (1%).[253,254] It is hypothesized that patients with MDS who acquire a variety of mutations could secondarily acquire homozygous loss of function of *PIGA*.[255] An alternative explanation is that an abnormal clone with the PNH anomaly arises first through selective pressure on stem cells as a result of autoimmune attack and evolves over time to MDS.[256] A diagnosis of PNH established by flow cytometric demonstration of GPI-anchored protein loss does not preclude a diagnosis of MDS if other criteria corroborate the diagnosis, even in the presence of overt clinical PNH and *PIGA* mutation. However, in most cases of MDS, the PNH clone is small (<5%).[94] If a patient with PNH develops significant marrow dysplasia or a clonal cytogenetic abnormality consistent with MDS, evolution to MDS should be strongly considered.

Idiopathic Cytopenia of Undetermined Significance (ICUS)

Patients who have persistent (>6 months), significant, and unexplained cytopenia but lack MDS-defining dysplasia, excess blasts, or an MDS-defining genetic abnormality are considered in the general category of idiopathic cytopenia of undetermined significance (ICUS). A bone marrow examination is required to diagnose ICUS because there must be documented absence of significant dysplasia in any

lineage or excess blasts and also absence of an MDS-associated cytogenetic abnormality on a complete bone marrow karyotype.[105,257] It is recommended that patients with ICUS be observed with periodic blood counts, and a repeated marrow examination should be performed if the cytopenias worsen significantly and remain unexplained. Over time, some patients will develop bona fide MDS or another myeloid neoplasm. Flow cytometry aberrations and mutations (see this chapter's section Clonal Hematopoiesis of Indeterminate Potential [CHIP] and Clonal Cytopenia of Undetermined Significance [CCUS]) may help predict the likelihood of ICUS progression to MDS or AML.[258]

Idiopathic Dysplasia of Undetermined Significance (IDUS)

Cytopenia is a sine qua non of MDS, and therefore patients who undergo bone marrow examination for any reason that shows significant dysplasia in one or more lineages but lack any cytopenia (during at least a 6-month period) cannot be diagnosed with MDS, even if an MDS-defining genetic abnormality is found. In such situations, it is important to consider other myeloid and nonmyeloid neoplasms, particularly rare MDS/MPN cases that may manifest dysplasia but lack significant cytopenia. Plasma cell myeloma and some bone marrow lymphomas can produce reactive dysplastic changes in marrow hematopoietic elements. Finally, secondary dysplastic changes in hematopoietic elements can be produced by a variety of non-neoplastic conditions, including infections and autoimmune disease, and by drugs, toxins, and metabolic deficiencies, as discussed previously. Indeed, just as patients with ICUS often progress to MDS or AML on follow-up, patients with idiopathic dysplasia of undermined significance (IDUS) often

subsequently are found to have neoplastic conditions. These are often neoplasms other than MDS, such as myeloproliferative neoplasms, AML, or MDS/MPN overlap disease.[259]

Germline Predisposition Conditions

As discussed previously, many MDS cases in children and some MDS cases in adults occur in the background of a germline predisposition syndrome, which may be unknown at the time of MDS diagnosis. Some of these conditions (particularly ones associated with thrombocytopenia, such as *RUNX1, ANKRD26,* and *ETV6* mutation) can exhibit dysplasia in the bone marrow, which is typically unilineage and is seen in megakaryocytes. This creates challenges in diagnosing the onset of bona fide MDS, which occurs frequently in patients affected by these germline predisposition conditions. The ICC proposes a set of features that indicate progression to MDS in these conditions: Either increased blasts should be present, or two of the following conditions: (1) a pathogenic somatic genetic aberration (mutation or cytogenetic abnormality); (2) one of the MDS-defining genetic abnormalities (delineated in Tables **44-5** and **44-6**); (3) development of a new cytopenia or progressive cytopenia, particularly in the context of increasing marrow cellularity; or (4) dysplasia seen in ≥10% of cells in two or three hematopoietic lineages.[178] In children, note that cytopenia levels should be age-adjusted based on each institution's reference range.

Non-Neoplastic Clonal Myeloid Proliferations

Clonal Hematopoiesis of Indeterminate Potential (CHIP) and Clonal Cytopenia of Undetermined Significance (CCUS)

Although some specific genetic abnormalities, such as *SF3B1* mutation or multihit *TP53,* are considered sufficient to diagnose MDS in a cytopenic patient, the same does not hold true for other genetic abnormalities. It is tempting to assume that a cytopenic patient with clonal hematopoiesis proven by the presence of MDS-type mutations has MDS. However, MDS-type mutations and gene copy number abnormalities have been found in the blood of healthy individuals who do not have MDS. Every individual has approximately 10,000 self-renewing hematopoietic stem cells, which progressively accumulate mutations as an individual ages (estimated at approximately 1.3 somatic mutations per stem cell per decade).[260] Most of this mutational "baggage" represents nonpathogenic so-called "passenger" mutations, but some affect key genes that confer growth advantage to the stem cell (driver mutations) and allow it to outcompete its unmutated neighbors. Eventually, the differentiating progeny of this expanded, mutated stem cell population are detectable by sequencing peripheral blood leukocytes. CHIP is proposed to encompass such individuals who have identifiable acquired genetic abnormalities but have no known diagnosable hematologic disease and no unexplained cytopenias. A minimal variant allele fraction of 2% is set as an arbitrary threshold for CHIP because it is likely that most, if not all, individuals harbor mutations in a small fraction of hematopoietic cells that will be detectable with increasingly sensitive sequencing technology.[67] The incidence of CHIP is estimated at approximately 5% to 10% of individuals older than 65 or 70 years of age and up to 18.4% of individuals older than 90 years of age; it is rare in those younger than 40 years of age.[261-263] Individuals with CHIP appear to be at modestly increased risk for development of a subsequent hematologic malignant neoplasm compared with age-

matched controls without CHIP, but this is only approximately 0.5% to 1% per year. Interestingly, such individuals are also at increased risk of death from causes other than hematologic neoplasms. It is currently unclear how individuals found to have CHIP should be managed, but at the time of this writing, they are not considered to have a neoplasm and do not warrant therapy. The related condition CCUS represents CHIP with the additional feature of a persistent unexplained cytopenia; looked at another way, CCUS can also be defined as ICUS with the additional feature of a myeloid-type somatic mutation or cytogenetic aberration that is not MDS defining.

VEXAS Syndrome

VEXAS (**V**acuoles, **E**1-enzyme, **X**-linked, **A**utoinflammatory, **S**omatic) syndrome is an autoinflammatory syndrome associated with a somatic mutation in the *UBA1* gene in hematopoietic cells. *UBA1,* which resides on the X chromosome, encodes a cytoplasmic E1 enzyme that is deficient when the gene is mutated. Given its presence on the X chromosome, male patients are much more frequently affected with VEXAS. Patients characteristically present with macrocytic anemia and have vacuolation of erythroid and myeloid precursor cells in the bone marrow.[264] Autoimmune diseases, particularly relapsing polychondritis, are a typical feature of the syndrome.[265] As with other non-neoplastic clonal cytopenias, MDS-defining morphologic dysplasia (or an MDS-defining genetic abnormality) is required to diagnose MDS in the setting of VEXAS syndrome; erythroid and myeloid vacuolization should not be taken into account when evaluating these lineages for morphologic dysplasia.[266]

The implications of MDS developing in the setting of VEXAS are uncertain, as these patients rarely develop increased blasts or progress to AML, indicating a uniquely indolent MDS behavior in this setting.[266] Given its relatively recent identification, further study is needed to clarify the relationship between VEXAS and MDS and other myeloid neoplasms and the optimal treatment approach to these patients, who often suffer significant clinical sequelae from their autoimmune diseases.

Other Neoplasms

Acute Myeloid Leukemia With Recurrent Genetic Abnormalities (AML-RGA) and <20% Blasts

Cytogenetic examination of the bone marrow and NGS studies are essential in the evaluation of all MDS and AML. One example of the critical importance of this testing is in identifying AML-RGA with <20% blasts.[267] The ICC mandates a diagnosis of AML in a patient presenting de novo with any AML-defining genetic aberrations, provided the bone marrow or blood blast percentage is at least 10%. Since it is unclear whether patients with AML-type recurrent genetic abnormalities but no increase in blasts benefit from intensive AML-type chemotherapy, further study is warranted to determine the appropriate classification and optimal therapeutic approach to the rare cases with <10% blasts and AML-RGA genetics. Nevertheless, is important to recognize and correctly diagnose AML-RGA in patients with 10% to 19% blasts because a misdiagnosis of MDS may lead to an unnecessary delay in the institution of potentially curative chemotherapy and poor patient outcome.[112] Whereas the incidence of MDS and MDS-related AML increases exponentially with age,[1] most subtypes of AML-RGA have an approximately flat incidence

throughout life, and these are often genetically simple, with no or few genetic abnormalities aside from the defining one.

Clues to suspecting a low–blast count AML-RGA versus MDS include frequent promyelocytes with Auer rods in AML with *PML*::*RARA*; abnormal eosinophils with mixed eosinophilic-basophilic granules and monocytic blast morphology in AML with *CBFB*::*MYH11*; blasts with "salmon-colored" cytoplasm, fine granules, and Auer rods in AML with *RUNX1*::*RUNX1T1*; and "cup-shaped" blasts in AML with mutated *NPM1*. These AML-RGA entities tend to occur in a much younger population than MDS but can also affect elderly individuals. Several additional cytogenetic subtypes of AML-RGA have been added in the ICC and proposed 5th edition WHO classification (see **Chapter 46**, Acute Myeloid Leukemia).[124,125] These include t(3;3)(q21;q26), inv(3)(q21q26), and other 3q26 cytogenetic abnormalities that involve the *MECOM* gene. Such cases tend to have prominent megakaryocytic dysplasia and often an increased platelet count.[113,268] In addition to AML-defining cytogenetic aberrations, two mutations, *NPM1* mutation and in frame mutation in the bZIP domain of *CEBPA,* are also considered to be AML-defining in the ICC, with a minimum blast count of 10%. In the proposed 5th edition WHO classification, *NPM1,* but not *CEPBA,* is considered to be AML-defining.

Primary Myelofibrosis

Mild reticulin fibrosis in marrow is common in MDS, presumably secondary to the release of stromal tissue growth factors from dysplastic precursors, similar to the pathogenesis of primary myelofibrosis (PMF).[212,213] Significant marrow fibrosis in MDS may lead to confusion with PMF. Although both diseases involve an

acquired clonal genetic abnormality of a multipotential marrow progenitor, the distinction has important clinical consequence, as the two diseases have different clinical courses and are treated differently. Splenomegaly is unusual in MDS, and the presence of any extramedullary hematopoiesis would tend to favor a diagnosis of PMF over MDS. A leukoerythroblastic peripheral blood smear picture, with numerous circulating nucleated erythroid forms, teardrop erythrocytes, and left-shifted granulocytes, is also more suggestive of PMF, although leukoerythroblastosis can also be seen in MDS with fibrosis. PMF typically has clusters of abnormal megakaryocytes in the marrow that are often enlarged with abnormal patterns of chromatin clumping, including hyperchromatic, bulbous-shaped nuclei. In MDS, the megakaryocytes are usually small with hypolobated, abnormally lobulated, or separated nuclei and rounded rather than scalloped nuclear contours; moreover, intrasinusoidal hematopoiesis is more commonly seen in PMF than MDS.[141] Whereas PMF usually shows an increased myeloid-erythroid ratio as a result of increased granulopoiesis, MDS is more often associated with erythroid predominance that may appear megaloblastoid, left-shifted, and dysplastic. Marked reticulin fibrosis, mature collagen fibrosis (indicated by marrow stromal staining on a trichrome stain), and osteosclerosis are more commonly seen in advanced stages of PMF and are uncommon in MDS. Cytogenetic abnormalities in PMF—including del(13q), del(20q), +8, and abnormalities of chromosomes 1, 5, 7, 9, and 21—largely overlap those of MDS and thus may not be informative in distinguishing these entities.[269] Conversely, *JAK2, MPL,* or *CALR* mutations are found in 80% to 90% of patients with PMF, and these mutations are rare in MDS, even in those cases with fibrosis.[35,270-272] Advanced phases of polycythemia vera and chronic

myeloid leukemia may also have marrow fibrosis and can also show dysplastic morphology, but clinical history and genetic studies (*JAK2, MPL, CALR,* and *BCR*::*ABL1* analyses) can usually reliably separate these entities from MDS.

Myelodysplastic/Myeloproliferative Neoplasms

Although most patients with MDS and neutropenia are unable to mount a significant leukocytotic response to an infection (even when exogenous myeloid growth factors are administered), some patients with MDS with a superimposed infectious or inflammatory process may develop a leukemoid reaction, mimicking MDS/MPN. The leukemoid reaction may include monocytosis mimicking CMML or left-shifted granulocytic elements mimicking atypical CML.[273] Complicating the issue, some patients with MDS subsequently develop monocytosis resembling CMML, which appears to represent a type of disease progression in MDS.[274] It is important to recognize these possibilities because patients with MDS are prone to infectious complications as a result of their neutrophil dysfunction, and the treatment and prognosis of an MDS patient with a leukemoid reaction differ from those of patients with various MDS/MPN entities. The presence of a known infectious or inflammatory clinical process should raise suspicion for a leukemoid reaction, and treatment of the underlying process should result in reversion to peripheral blood counts typical of the underlying MDS.

A spontaneous and persistent development of leukocytosis, thrombocytosis, or monocytosis in a patient previously diagnosed with MDS does not mandate reclassification as MDS/MPN. Instead, these patients should retain the label of MDS, with the elevated counts noted in the report. Such changes in the disease phenotype can

be harbingers of disease progression and poorer outcome.[274] Conversely, persistent leukocytosis (≥13 × 10^9/L) and/or absolute and relative monocytosis (≥0.5 × 10^9/L and 10% of all leukocytes) in any myeloid neoplasm at diagnosis that are not attributable to an underlying infectious or inflammatory process exclude MDS and require classification as MDS/MPN or MPN, even if cytopenias in other lineages are present. Notably, in the ICC and proposed 5th edition WHO classification, the threshold of absolute monocytosis defining CMML has been lowered from 1.0 to 0.5 × 10^9/L; thus, cases with relative monocytosis and 0.5 to 0.9 × 10^9/L monocytes (so-called "oligomonocytic" CMML)[275] that would have previously been classified as MDS are now classified as CMML.

Large Granular Lymphocytic Leukemia

As opposed to most lymphoid leukemias, which present with overt lymphocytosis, patients with large granular lymphocytic (LGL) leukemia typically present with cytopenias and minimal or no lymphocytosis, thus potentially mimicking MDS. Compounding the issue, reactive dysplastic changes may be seen in the maturing hematopoietic cells in LGL leukemia, and the neoplastic T-cell infiltrates in the bone marrow biopsy sample may be subtle. Conversely, reactive lymphoid aggregates may be present in MDS. In general, patients with LGL leukemia present predominantly with neutropenia, whereas an anemic presentation is more common in MDS. Flow cytometry identifies an expanded population of immunophenotypically aberrant CD8-positive, CD57-positive T cells, and polymerase chain reaction (PCR) study of blood or marrow discloses a clonal T-cell receptor rearrangement in LGL leukemia.[276] Whereas the neoplastic T cells in LGL leukemia occur in an interstitial

and often intrasinusoidal pattern in the bone marrow biopsy sample (best revealed by immunohistochemistry for cytotoxic markers, such as TIA-1, perforin, or granzyme), any increased lymphoid cells in MDS typically form nonparatrabecular aggregates. If *STAT3* or *STAT5B* mutations are identified on NGS of a putative MDS case (particularly if flow cytometry discloses increased large granular lymphocytes with an aberrant immunophenotype), an alternative diagnosis of LGL leukemia as a cause of the cytopenias should be considered.[277] Rarely, MDS and LGL leukemia may occur together, and *STAT3* mutations and small clonal T-cell populations that typify LGL leukemia have been identified in MDS patients.[278,279] Thus, in some cases, it may be difficult to distinguish LGL leukemia from MDS with an expanded clonal T-cell population. Close clinical follow-up may be the most prudent approach in such cases.

Etiology and Pathogenesis

A variety of agents and diseases are associated with an increased incidence of MDS. Germline predispositions, which have been previously discussed, typically result in MDS in childhood, but they can also present in adulthood.[190] A variety of exposures (ionizing radiation, agents that cause cross-link DNA damage, benzene, other solvents and petrochemicals, agricultural or farming chemicals, smoking, hair dyes) have been linked to an increased incidence of MDS and AML. With some (alkylating agents), the association is strong; in others, the contribution to causation is less definite. Some cytotoxic therapies may not actually initiate the abnormal clone through DNA damage, but rather appear to promote the expansion of

a preexisting low-level mutated stem cell clone through selection in the marrow microenvironment.[185,235]

MDS is a clonal proliferation of cells originating from an abnormal hematopoietic stem cell: the stem cell is thought to acquire a founding genetic abnormality (or more often multiple cooperating abnormalities) that gives it a growth advantage, allowing its differentiating progeny to progressively replace normal hematopoiesis. This model is supported by the presence of recurring mutations and karyotype abnormalities in most MDS cases and the fact that these mutations can be traced back to the most primitive, self-renewing multipotent hematopoietic stem cells that bear the original growth-promoting mutations.[69] Ultimately, future MDS therapies should be directed against the MDS stem cells, but these are difficult to target owing to their quiescence and are seldom eradicated with most current therapies.

Most MDS cases bear not one but multiple concurrent genetic abnormalities whose interactions are complex and poorly understood. In **MDS with del(5q),** there is presumed loss of a tumor suppressor gene or genes in the deleted region. Haploinsufficiency of the *RPS14* gene that encodes a ribosomal structural protein appears to contribute to the disease phenotype, possibly through p53 pathway activation.[280] Deficiency of two micro-RNAs, miR-145 and miR-146a, in the deleted region may also contribute to the megakaryocyte abnormalities and thrombocytosis characteristic of this MDS subtype.[281]

Splicing genes are mutated in over 50% of MDS cases. In MDS cases with mutation in the spliceosome complex gene *SF3B1*, there is evidence that differential splicing of *ABCB7* and other gene products involved in mitochondrial iron metabolism may underlie the

formation of ring sideroblasts.[282-284] However, data in mouse models are conflicting as to whether *SF3B1* haploinsufficiency truly creates an MDS phenotype.[285,286] Epigenetic gene regulation through histone modification and DNA methylation is also perturbed in MDS, with recurring somatic mutations in epigenetic regulator genes such as *EZH2, ASXL1, DNMT3A, TET2, IDH1,* and *IDH2*.[287]

There is increasing interest in the role of the bone marrow microenvironment in contributing to MDS pathogenesis. A number of abnormalities have been identified in cytokines (such as tumor necrosis factor-α and interleukin-32) and in stromal cell signaling to CD34-positive stem cells in patients with MDS.[288] There is also evidence that the so-called "niche" (the physical sites where hematopoietic stem cells reside and are supported by surrounding cells, extracellular matrix, and soluble factors) may be altered in myeloid neoplasms such that it fosters the growth and self-renewal of MDS stem cells over normal stem cells.[289,290] The gene mutated in Schwachman-Diamond syndrome, *SBDS,* encodes a protein necessary for creation of the stem cell niche by osteoprogenitor cells.[291,292] In some murine models, manipulation of the osteoblastic stem cell niche has been shown to induce MDS.[293] Abnormal expression of β-catenin in osteoblasts associated with activated Notch signaling has also been implicated in MDS pathogenesis.[294] At the time of this writing, it is unclear how these stromal abnormalities coordinate with the genetic abnormalities in the MDS stem cells to create the disease phenotype; it is tempting to speculate that microenvironmental abnormalities may be particularly important in the approximately 10% of MDS cases that lack demonstrable genetic abnormalities in hematopoietic cells, but this remains to be proven.

Conclusion

MDS is a heterogeneous myeloid neoplasm characterized by clonal, mutated hematopoiesis, morphologic dysplasia, and infective hematopoiesis resulting in cytopenia. The role of the mutation profile and bone marrow microenvironment in creating the phenotype of each unique disease is complex and remains elusive. The patient's genetic background (germline predisposition conditions) and extrinsic factors such exposure to cytotoxic chemotherapy also contribute to MDS heterogeneity. Whereas diagnostic tools are rapidly expanding, the diagnosis of MDS is still based on the secondary disease features—cytopenias and dysplastic morphology—that are neither completely specific nor pathognomonic. It is nevertheless important that MDS be diagnosed and subclassified accurately because of the prognostic and therapeutic implications of the specific disease subtypes. MDS has an extensive and difficult set of differential diagnoses, some of which can be ruled in or out only by clinical follow-up. It is hoped that further characterization of genetic abnormalities and their role in dictating the disease pathogenesis will result in improved diagnostic capabilities and clarification of important clinical and biological subsets of this intriguing set of diseases.

Pearls and Pitfalls

- A good bone marrow sample (aspirate smear or touch preparation and biopsy section) and a full complement of ancillary tests (complete blood count with differential and

peripheral smear review, bone marrow cytogenetics, and NGS studies) are essential for the correct diagnosis and classification of MDS. Flow cytometry to identify recurrent immunophenotypic abnormalities are also helpful.

- Most of the features of MDS (cytopenias, dysplastic morphology, genetic abnormalities, and flow cytometry abnormalities) are neither pathognomonic nor a sine qua non for the diagnosis. Ideally, multiple abnormalities should be present to support the diagnosis. However, at least one (unexplained) cytopenia is an absolute requirement for a diagnosis of MDS.
- The clinical behavior of MDS is highly heterogeneous, ranging from nonprogressive disease with survival approaching that of age-matched peers to rapidly progressive and fatal disease; this heterogeneity is captured in the various MDS disease subtypes and in comprehensive risk-stratification models.
- The differential diagnosis of MDS is extensive, and careful exclusion of other possible non-MDS entities is imperative before a definitive diagnosis is rendered.

Chapter 45: Myeloid and Hematologic Neoplasms With Germline Predisposition

Katherine R. Calvo, and Olga K. Weinberg

OUTLINE

Definition and Introduction

Classification

Types of Germline Mutations and Genetic Testing Considerations

General Considerations Regarding Bone Marrow Morphology and Diagnosis of Myeloid Malignancy in the Setting of Germline Predisposition

Synonyms and Related Terms

Hematologic Neoplasms with Germline Predisposition Without A Constitutional Disorder Affecting Multiple Organ Systems

- Myeloid Neoplasm With Germline CEBPA Mutation
- Myeloid or Lymphoid Neoplasms With Germline DDX41 Mutation
- Myeloid or Lymphoid Neoplasms With Germline TP53 Mutation

Hematologic Neoplasms with Germline Predisposition Associated with A Constitutional Platelet Disorder

- Myeloid or Lymphoid Neoplasms With Germline RUNX1 Mutation
- Myeloid Neoplasms With Germline ANKRD26 Mutation
- Myeloid or Lymphoid Neoplasms With Germline ETV6 Mutation

Hematologic Neoplasms with Germline Predisposition Associated with A Constitutional Disorder Affecting Multiple Organ Systems

- Myeloid Neoplasms With Germline GATA2 Mutation
- Myeloid Neoplasms With Germline SAMD9 or SAMD9L Mutation
- Myeloid Neoplasms Associated With Bone Marrow Failure Syndromes

Juvenile Myelomonocytic Leukemia Associated With Neurofibromatosis, Noonan Syndrome, or Noonan-Syndrome-Like Disorders (CBL-Syndrome)

Definition and Introduction

Germline predisposition to hematologic neoplasia occurs in individuals with inherited or de novo mutations in the germline in genes that confer increased risk of developing hematologic malignancy or cancer. Additional acquired genetic alterations cooperate with underlying germline mutations to drive the development of cancer, which often occurs at an earlier age than corresponding sporadic neoplasms. Germline predisposition to cancer was demonstrated as early as early as 1866 when French physician Paul Broca published the *Broca Report* showing four generations of breast cancer, suggesting inherited predisposition. A century later in 1969, Drs. Li and Fraumeni described families with

increased incidence of solid tumors and leukemia with an autosomal dominant inheritance pattern, which later was shown to be caused by germline mutations in *TP53*.[1,2] Classical bone marrow failure (BMF) syndromes, including Fanconi anemia (FA), were known to have increased risk of cancer and myeloid malignancy. In 1999, germline mutations in *RUNX1* (i.e., *CBFA2*) were discovered in six families with familial platelet disorder with propensity to develop myeloid malignancy.[3] Since then the number of genes known to be associated with germline predisposition to myeloid malignancy have grown, largely aided by next-generation sequencing (NGS) technology. There is increased recognition of the contribution of germline mutations to the development of myeloid and other hematologic malignancies, particularly in pediatric, adolescent, and young and middle-aged adults.

Classification

In 2017 the revised WHO 4th ed. devoted a new chapter to myeloid neoplasms with germline predisposition underscoring the importance of properly identifying these patients.[4] The germline mutations were divided into three major categories: (1) myeloid malignancies with germline predisposition without a preexisting disorder *(CEBPA, DDX41)*; (2) myeloid neoplasms with germline predisposition and preexisting platelet disorders (*RUNX1, ANKRD26,* and *ETV6*); and (3) myeloid neoplasms with germline mutation associated with other organ disfunction (*GATA2,* inherited marrow failure syndromes, telomere biology disorders, juvenile myelomonocytic leukemia [JMML] associated with neurofibromatosis and Noonan/Noonan-like disorders, and Down

syndrome). In 2022, the International Consensus Classification (ICC)[5,6] and the WHO 5th ed. classification[7] expanded the number of recognized genes associated with germline predisposition (**Box 45-1**). Both the ICC and the 2022 WHO 5th ed. added *TP53, SAMD9,* and *SAMD9L*. The ICC broadened the title to *hematologic neoplasms with germline predisposition*, emphasizing that many germline mutations predisposing to myeloid malignancy also predispose to lymphoid neoplasia. The ICC also added a category of germline predisposition to acute lymphoblastic leukemia (*IKZF1* and *PAX*). The WHO 5th ed. classification incorporated myeloid neoplasms with germline predisposition under a broader category of secondary myeloid neoplasms. This approach was not taken by the ICC, as many patients with germline predisposition and hematologic neoplasms present to clinicians with primary disease. Both the ICC and WHO 5th ed. classifications allow for incorporation of new germline predisposition genes as they are discovered and compelling evidence emerges.

* Included in the WHO 5th ed. 2022 classification.

‡ Down syndrome, and germline mutations in *ETV6* or *TP53,* also predispose to acute lymphoblastic leukemia.

† Included in the revised WHO 4th ed. 2016 classification.

Recognition of germline predisposition to hematologic malignancy is critical for proper patient management, surveillance of disease progression, genetic counseling, and for screening potential matched related donors for hematopoietic stem cell transplantation (HSCT). Many patients with myeloid malignancies associated with underlying germline mutations require tailored chemotherapy regimens to avoid toxicity or poor outcome. Germline mutations may have variable penetrance and expressivity even within family members harboring the same mutation. Age of onset of disease manifestations or malignancy onset may vary widely. In general, germline

predisposition should be considered in patients with a history of multiple cancers, first- or second-degree relative with a hematologic malignancy or solid tumor at a relatively young age (<50), thrombocytopenia or BMF preceding a diagnosis of myelodysplastic syndrome (MDS)/acute myeloid leukemia (AML), immunodeficiency, warts, lymphedema, early graying of hair, pulmonary fibrosis, or other physical stigmata associated with specific germline predisposition syndromes (**Box 45-2**). It is important to note that some patients with germline mutations in genes that are classically associated with physical stigmata or syndromic features may not have overt stigmata or syndromic features, or they may be subtle on physical exam (i.e., FA).

Recognition of underlying germline mutation is critical for any patient undergoing HSCT who will be transplanted using a related donor. Phenotype is not always an indicator of genotype because of variable penetrance and expressivity. For this reason, all potential related donors should be screened for the patient's germline mutation, regardless of the health of the donor. Multiple reports have shown that inadvertent use of a related donor harboring the same germline mutation as the patient can result in donor-derived MDS/AML, graft failure, or poor outcome.[8-11] Knowledge of a germline mutation also has important implications for offspring and other family members. Genetic counseling plays an important role in patient management.

Types of Germline Mutations and Genetic Testing Considerations

Somatic or acquired mutations occur in specific cells and may give rise to cancer associated with the tissue of the cell of origin. The majority of cancer in older individuals is associated with somatic mutations. In contrast, germline mutations are present in all of the cells of the body, and may be inherited and present in multiple family members. De novo germline mutations are present in the patient but not detected in the parents. In this setting the original mutation may have occurred in a germ cell (i.e., sperm or ova), or in the fertilized egg during embryogenesis.[12] Although de novo germline mutations are not present in parents or siblings, they may be passed on to offspring.

Germline mutations predisposing to cancer may have autosomal dominant, autosomal recessive, or X-linked inheritance patterns. In general, autosomal recessive mutations are homozygous and require two mutated copies of the gene in each cell, which are inherited from both parents who are carriers and may have no evidence of disease. Genes with autosomal dominant inheritance are associated with heterozygous germline mutations with one mutated copy of the gene that is typically inherited from one parent who may or may not have evidence of disease, and may be associated with a family history of disease. In patients with de novo germline autosomal dominant mutations, they are the first person in their family to have the mutation and it may be passed on to their offspring. X-linked mutations are in genes on the X chromosome and may be recessive or dominant. In diseases with X-linked recessive mutations, males are most often affected; females are typically nonaffected as females have two copies of the gene (one mutated and one wild type), while males have only one mutated copy of the gene. Females may be

affected if the female has or develops monosomy X, or via X-inactivation/lionization. X-linked dominant mutations affect both males and females. The development of hematologic malignancy in the setting of germline predisposition is associated with acquisition of additional genetic alterations that cooperate with the underlying germline mutation(s) to drive oncogenesis.

Box 45-2 Germline Testing Considerations

1. Consider germline testing for patients with hematologic malignancy (HM) and any of the following:

- Two or more cancers, including HM
- Family history of HM, solid tumor, hematologic abnormality within two generations
- Pediatric patients and young adults (<50 yrs) with HM (caveat: germline mutations in *DDX41* are associated with HM development in similar age range of sporadic HMs)
- Preceding history of thrombocytopenia, bone marrow failure, immunodeficiency, warts, lymphedema, early graying of hair, pulmonary fibrosis, dystrophic nails, physical stigmata, or other syndromic features associated with germline predisposition syndromes
- High variant allele frequency (VAF) (30%–60%) of pathogenic mutation in germline predisposition genes detected on next-generation sequencing (NGS) profiling suggestive of possible germline mutation

- Persistence of pathogenic mutation at high VAF on serial NGS tests before and after chemotherapy treatment
- Biallelic mutations in genes associated with germline predisposition to HM (e.g., *CEBPA, RUNX1, DDX41*)
- Plan to undergo hematopoietic stem cell transplantation (HSCT) using related donor—testing to inform donor selection to ensure donor does not harbor same germline mutation as patient, if germline mutation is present
    - Therapy-related myeloid neoplasms (MN)

2. Tissue for germline testing:

- Gold standard:
    - Cultured fibroblasts from skin biopsy (no contamination from hematopoietic cells)
- Other possible samples:
    - Skin biopsy with wash-out of peripheral blood
    - Buccal swab—may be contaminated with peripheral blood
    - Hair follicles—may yield low genomic DNA
- Not recommended:
    - Peripheral blood or bone marrow—cannot reliably differentiate somatic from germline mutations
    - Saliva—contamination with peripheral blood
    - Nail clippings—possible contamination with monocytes

3. Additional testing considerations:

- Chromosomal breakage assay—informative for Fanconi anemia diagnosis
- Flow-fluorescence in situ hybridization (FISH) for telomere length—informative for diagnosis of telomeropathies

- Germline testing for young patients with bone marrow failure (<50 yrs) for early detection of germline mutation to inform surveillance for disease progression and HM

Given the widespread use of NGS panels on blood or marrow specimens in clinical hematology/oncology practice, many cases of myeloid malignancies with germline predisposition have been initially suspected on NGS panels designed to detect somatic mutations. A high variant allele frequency (VAF) above 30% may suggest germline mutation; however, somatic mutations can also have high VAF and germline testing is recommended for confirmation. Genetic testing of a germline tissue source, such as cultured fibroblasts from a skin biopsy, is the gold standard for confirming germline mutations (**Box 45-2**). Buccal swabs may contain contamination from blood cells and are not ideal germline tissue sources. Hair follicles have been used by some labs to identify germline mutations; however, the yield of genomic DNA may be low. Nail clippings may contain monocytes and are not ideal. If the same mutation is present in multiple family members, this provides strong evidence for the germline nature of the mutation. Other clues include persistence of a pathogenic mutation at a high VAF after chemotherapy treatment; and HMs with double mutations in certain genes, possibly representing an underlying germline mutation and a somatic hit in the same gene, which is common for some germline predisposition genes (e.g., *CEBBPA, RUNX1,* and *DDX41*).

Germline mutations are often broadly classified as missense, nonsense, or null mutations. Mutations may consist of large deletions or translocations that may be difficult to identify on NGS platforms. Notably, some genes have germline mutations in

noncoding regions involving intronic enhancers (e.g., *GATA2*) or 5′ promoter regions (e.g., *ANKRD26*).[13,14] Mutations in noncoding regions can be missed by whole exome sequencing or targeted panels that do not cover these regions. Recently there is more awareness of pathogenic synonymous germline mutations that alter RNA sequence affecting RNA splicing sites without altering protein sequence. If regions of a germline mutation are covered on a routine NGS panel designed to identify somatic mutations, the germline mutation may be identified; however, it will not be possible to definitively determine whether the mutation is germline or somatic if hematopoietic cells are used as the source for testing. If suspicion of a germline predisposition gene mutation is high but not found on routine testing, subsequent testing at a specialized laboratory may be considered. Many laboratories specialized in germline testing use enhanced whole exome sequencing (WES) that incorporates probes for noncoding regulatory and intronic regions known to contain hotspot loci for predisposition mutations.[15]

General Considerations Regarding Bone Marrow Morphology and Diagnosis of Myeloid Malignancy in the Setting of Germline Predisposition

There is no specific morphologic or immunophenotypic finding diagnostic of MDS/AML with germline mutation. There are typical pathologic features that are associated with some germline mutations that will be discussed in the genetic sections. The presence of a germline mutation predisposing to MDS/AML is not diagnostic of myeloid malignancy until unequivocal features of overt malignancy develop. Importantly, bone marrow of many patients

with germline mutations may show at baseline dysplastic features that remain stable and may not progress to MDS or AML for many years or may never progress depending on the inherent risk of malignancy conferred by the specific genetic mutation. Evaluation of bone marrow morphology requires expertise and must be interpreted with caution in order to avoid overdiagnosis of MDS. It is recommended that these cases not be interpreted as MDS unless additional supporting features are present, including frank multilineage dysplasia, increased blasts, increasing cellularity in the setting of worsening cytopenias, or emergence of MDS or AML defining cytogenetic or molecular genetic abnormalities (**Box 45-3**). This is particularly critical for patients with familial platelet disorders who typically show baseline dysmegakaryopoiesis that is associated with isolated thrombocytopenia caused by mutations in *RUNX1, ANKRD26,* or *ETV6* in the absence of MDS. Conversely, some patients may have borderline or minimal evidence of dysplasia in a hypocellular marrow, with emergence of monosomy 7 or other MDS-defining cytogenetic abnormality indicative of progression to MDS. Not all cytogenetic abnormalities warrant a diagnosis of MDS and some may be associated with stable disease. MDS-defining genetic abnormalities include: monosomy 7; monosomy 5; del(7q); del(5q); multihit *TP53* mutations—defined as two or more distinct *TP53* mutations each with VAF ≥10%, or a single *TP53* mutation with (1) 17p deletion on cytogenetics, (2) VAF of ≥50%, or (3) copy neutral loss of heterozygosity (LOH) at the 17p*TP53* locus; *TP53* mutation (VAF ≥ 10%) and complex karyotype (often with loss of 17p); or *SF3B1* mutation (VAF ≥ 10%).[5] Clonal hematopoiesis is not uncommon in patients with germline predisposition and must be

interpreted in the context of the specific germline predisposition and the bone marrow/peripheral blood findings. Of note, monoallelic *TP53* mutations with low VAF are common in patients with Shwachman-Diamond syndrome; but biallelic mutations are associated with myeloid malignancy. The morphologic diagnosis of MDS in patients with germline predisposition may be challenging and requires close collaboration between clinicians and pathologists to arrive at the appropriate diagnosis and treatment. Myeloid neoplasms should be diagnosed with indication of the associated germline mutation or syndrome; for example, AML with germline mutation in *CEBPA,* or JMML associated with Noonan syndrome. If a patient is diagnosed with MDS/AML and a germline mutation is subsequently identified, the diagnosis can be modified to incorporate the underlying germline mutation.

Box 45-3 Features Associated With Progression to Myelodysplastic Syndrome in Patients With Germline Predisposition*

Two out of three of the following:

- Acquired pathogenic genetic alteration
  - Monosomy 7; monosomy 5; del(7q); del(5q); multihit *TP53* mutations, defined as two or more distinct *TP53* mutations each with VAF ≥ 10%, or a single *TP53* mutation with (1) 17p deletion on cytogenetics, (2) VAF ≥ 50%, or (3) copy neutral LOH at the 17p*TP53* locus; *TP53* mutation (VAF ≥ 10%) and complex karyotype (often with

loss of 17p); or *SF3B1* mutation (VAF ≥ 10%) are considered MDS-defining[†]

- Cytopenia in a new lineage(s) or progressive cytopenia,[‡] particularly in the context of increasing marrow cellularity
- Multilineage dysplasia[§]

Or:

- Increased blasts
  - ≥5% in marrow; ≥2% in peripheral blood

---

[*] These are guidelines and are not intended as absolute criteria; clinical judgment must be applied in each case.

[‡] In adults, cytopenias are defined as hemoglobin <12 g/dL in females and <13 g/dL in males, absolute neutrophil count $<1.8 \times 10^9$/L, or platelets $<150 \times 10^9$/L. In children, cytopenia is defined according to age-adjusted values for hemoglobin, absolute neutrophil count, and platelet count.

[†] Genetic alterations should be interpreted in the context of the specific germline condition. Progression to acute myeloid leukemia (AML) may occur if AML-defining genetic abnormalities are present or criteria is met for AML. Progression to chronic myelomonocytic leukemia (CMML) or myelodysplastic syndrome (MDS)/myeloproliferative neoplasm (MPN) may also occur.

[§] Baseline marrows in patients with germline mutations may show evidence of dyspoiesis, hence, care must be made not to overinterpret dysmorphology as criteria for MDS in the absence of additional supporting evidence. Patients with

germline mutations in *RUNX1*, *ANKRD26*, and *ETV6* with isolated thrombocytopenia commonly show megakaryocytic atypia at baseline, and as a sole finding this is not sufficient for a diagnosis of MDS. Dysplasia is defined as dysplastic cytologic changes in ≥10% of erythroid cells, ≥10% of granulocytic cells, and/or ≥10% of megakaryocytes.

Synonyms and Related Terms

Inherited hematologic neoplasms; familial myelodysplastic syndromes/acute leukemias.

Hematologic Neoplasms with Germline Predisposition Without A Constitutional Disorder Affecting Multiple Organ Systems

Myeloid Neoplasm With Germline *CEBPA* Mutation

CEBPA is a single-exon gene located on chromosome 19q13.1 that encodes for CCAAT/enhancer-binding protein-α, a lineage-specific basic leucine zipper (bZIP) transcription factor. The *CEBPA* zipper domain is required for dimerization, and the adjacent basic region is responsible for DNA binding, thereby promoting transcription of target genes.[16-18] The N terminus is unique to *CEBPA,* containing two transactivation domains that regulate transcription control and protein interaction.[17] The mRNA may be translated into either a full-length 42-kDA isoform (p42) or a truncated 30-kDa (p30) isoform, both of which can homodimerize or heterodimerize with other CEBP

proteins to regulate genes involved in cell differentiation, survival, metabolism, growth, and inflammation.[19]

The inheritance of a germline *CEBPA* mutation predisposes to the development of AML with autosomal dominant inheritance and was first described in 2004.[20] Germline mutated CEBPA-associated AML is defined as the presence of a heterozygous germline *CEBPA* pathogenic variant in an individual with AML. Progression to AML is frequently associated with an acquired mutation in the remaining wild-type CEBPA allele.[21,22] The germline (often protein-truncating) mutation commonly affects the N terminus, whereas the acquired mutation arises in the C-terminal bZIP region (predominantly missense or in-frame indels).[23] Although numbers are limited, families with germline N-terminal mutations display a higher degree of penetrance (~90%) compared with fewer families harboring germline C-terminal mutations (~50%).[21]

Tawana and colleagues noted a >90% remission rate in patients with CEBPA-associated familial AML but found a 50% cumulative incidence of relapse, with some patients relapsing three or four times.[21] Molecular sequencing of five patients' tumors at the time of relapse revealed that they harbored new C-terminus somatic mutations, representing the development of a second primary AML rather than true disease relapse.[21] This pattern of progression likely underlies the clinical observations that patients with AML and germline *CEBPA* mutations have a good outcome yet are prone to second leukemias that continue to be sensitive to chemotherapy, unlike true relapsed disease. Up to 11% of presumed sporadic AML with biallelic *CEBPA* mutations may harbor a germline *CEBPA* mutation.[24]

Myeloid or Lymphoid Neoplasms With Germline *DDX41* Mutation

DDX41 belongs to the DEAD-box helicase family of genes that have been characterized in multiple cellular roles, composed of 17 exons, and is encoded on the distal end of the long arm of chromosome 5.[25] *DDX41* encodes a member of the DEAD-box ATP-dependent RNA helicases, which are involved in premRNA splicing, RNA processing, ribosome biogenesis, and small nucleolar RNA processing.[26,27] In addition, DDX41 interacts with intracellular DNA in dendritic cells and macrophages, and activates innate immunity through the stimulator of interferon genes (STING)-interferon pathway.[28,29]

DDX41 germline mutations are clinically associated with an increased lifetime risk of myeloid neoplasms, including the early presentation of idiopathic cytopenia of undetermined significance (ICUS).[30] Other diseases reported to be associated with *DDX41* mutations include myeloproliferative neoplasms, chronic myeloid leukemia, multiple myeloma, myelodysplastic syndrome (**Fig. 45-1**), and acute myeloid leukemia.[27,31,32] Lymphoid neoplasms have also been described but are less common with germline *DDX41* mutations. In a recently published study using a multinational cohort, *DDX41* germline mutations account for about 80% of patients with myeloid neoplasms with germline predisposition.[33] In contrast to other hereditary hematologic malignancies, *DDX41* mutation is associated with late onset myeloid neoplasms typically in the 6th decade, often occurring after years of typically mild cytopenia, or macrocytosis. While germline *DDX41* mutations should be considered in patients with a personal or family history of

hematologic malignancy, a family history of malignancy is often lacking.[26]

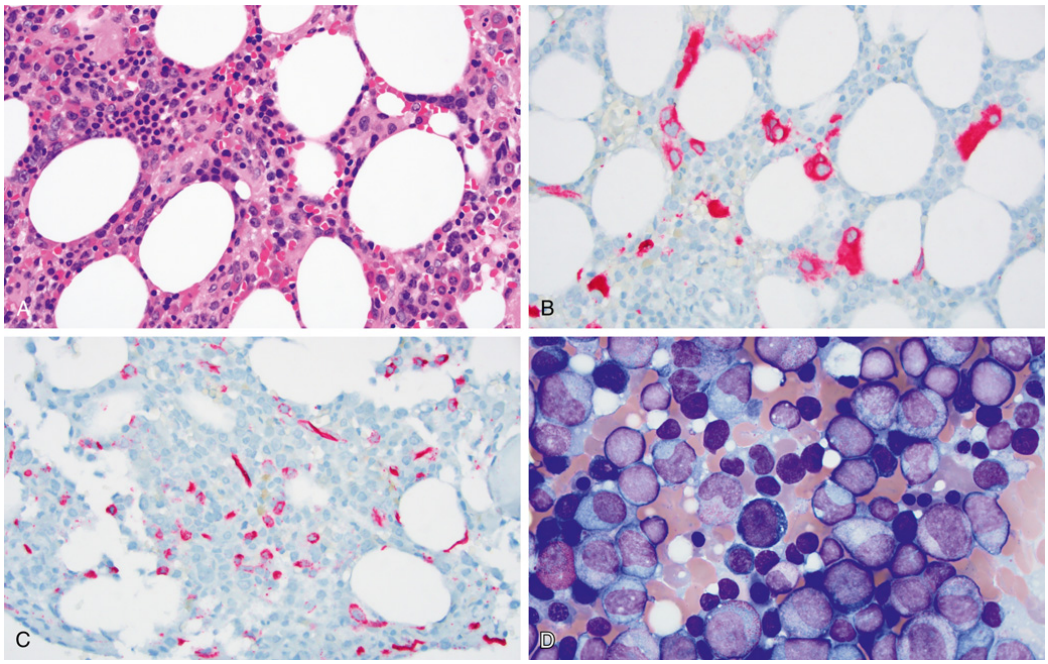

FIGURE 45-1 Myelodysplastic syndrome with excess blasts (ICC) and germline *DDX41* mutation.Bone marrow from a male in his 6th decade with a history of progressive cytopenias and myelodysplastic syndrome (MDS) in at least one other family member. **A,** The bone marrow was normocellular for age with evidence of dysplastic hypolobated megakaryocytes on hematoxylin and eosin (H&E) stain. **B,** CD61 IHC showed multiple dysplastic megakaryocytes with hypobated nuclei and micromegakaryocytes. **C,** CD34 IHC showed 5% to 9% increased positive cells consistent with blasts, confirmed on flow cytometry as aberrant myeloblasts with downregulated expression of CD38. **D,** Bone marrow biopsy touch prep showed left shift in myeloid precursors and increased blasts.

> Cytogenetic analysis was normal. Next-generation sequencing (NGS) myeloid mutation panel performed on bone marrow detected two *DDX41* mutations, one at 50% VAF and the other at 19% VAF. Testing on skin biopsy confirmed presence of a germline *DDX41* mutation. This case may also be diagnosed as MDS with increased blasts and germline *DDX41* mutation (MDS-IB-1) (WHO 5th ed.).

AML with germline *DDX41* mutation is often associated with a second acquired *DDX41* mutation. Bone marrow is often hypocellular with a borderline increase in blasts with mostly normal immunophenotype and with normal karyotype. These features make the initial diagnosis of this inherited AML more challenging than other hereditary hematologic predisposition syndromes. When assessing the frequency of *DDX41*-mutated variants across the spectrum myeloid neoplasms, *DDX41* variants had the highest representation in high-risk MDS and secondary AML.[33]

Myeloid or Lymphoid Neoplasms With Germline *TP53* Mutation

Transcription factor p53, encoded by the *TP53* gene, is a key tumor suppressor gene with protean functions associated with preservation of genomic balance, including regulation of cellular senescence, apoptotic pathways, metabolism functions, and DNA repair.[34] Li-Fraumeni syndrome (LFS) is a dominantly inherited condition caused by pathogenic germline variants in the TP53 tumor suppressor gene.[35,36] Patients with LFS are predisposed to a range of

neoplasms such as sarcomas, adrenocortical carcinoma, breast cancer, medulloblastoma, choroid plexus carcinoma, and anaplastic rhabdomyosarcoma.[36] Approximately 50% of individuals with LFS will develop cancer by age 30 years, with a lifetime risk of up to 75% in men and almost 100% in women.[37] Incidence of leukemias in LFS is approximately 4%[38] predominantly hypodiploid acute lymphoblastic leukemia (ALL) and therapy-related myeloid disorders including AML and MDS.[1,39,40] Genome-wide studies suggest that germline variants are more frequent than estimated prevalence of LFS, suggesting that many carriers of potentially pathogenic mutations may not develop the syndrome.[41] Carriers of a germline *TP53* mutation who are detected in a clinical context have a penetrance of 80% at age 70 and penetrance varies according to age, sex, and mutation type. Temporal tumor patterns show distinct phases, with childhood phase (0–15 years, 22% of all cancers) characterized by adrenal cortical carcinoma, choroid plexus carcinoma, rhabdomyosarcoma, and medulloblastoma; early adulthood phase (16–50 years, 51%) including breast cancer, sarcomas, leukemia, astrocytoma, and glioblastoma, colorectal, and lung cancer; and late adulthood phase (51–80 years, 27%) including pancreatic and prostate cancer.[41]

Whereas *TP53* alterations are generally rare in ALL, they are almost universally present in the low hypodiploid subtype of ALL, approximately 50% of which are germline in nature.[42] A recent study involving 3801 children with ALL showed that LFS-associated ALL accounts for less than 1% of ALL cases and was associated with inferior event-free survival as well as overall survival, and higher risk of second malignant neoplasms.[43] Observations show that more

than half of *TP53* mutations in low-hypodiploid ALL in children are also present in nontumoral cells, indicating that low-hypodiploid ALL is a manifestation of LFS. *TP53* mutations in AML are associated with older age, lower blast counts (both in the bone marrow and in the peripheral blood), adverse risk karyotypes, and exposure to antecedent chemotherapy. Therapy-related AML and MDS frequently occur in patients with LFS, likely related to the patients' extensive cancer history and prior myelosuppressive treatments. Cytotoxic agents like alkylating agents and topoisomerase inhibitors, as well as radiation therapy, are known to be associated with therapy-related MDS/therapy-related AML.[44]

Hematologic Neoplasms with Germline Predisposition Associated with A Constitutional Platelet Disorder

Hematologic neoplasms with germline predisposition associated with constitutional platelet disorders include germline mutations in *RUNX1, ANKRD26,* and *ETV6*. There are important baseline morphologic features seen in all three of these disorders that are critical for hematopathologists to recognize. Patients may have isolated thrombocytopenia with normal platelet size and dysmegakaryopoiesis in the marrow in the setting of stable nonmalignant disease for decades. Dysmegakaryopoiesis with small hypolobated megakaryocytes or forms with separated nuclear lobes is often seen in the setting of isolated thrombocytopenia indicative of inherent abnormal megakaryopoiesis with impaired proplatelet formation, and not indicative of MDS in the absence of other criteria supporting a diagnosis of MDS.[45-47] Because of baseline

dysmegakaryopoiesis, many patients with germline *RUNX1* and *ANRD26* mutations are overdiagnosed or misdiagnosed with MDS-with single lineage dysplasia.[48] Bona fide progression to MDS or other myeloid malignancy is typically associated with increased marrow cellularity, emergence of new cytopenias (in addition to thrombocytopenia) or cytoses, multilineage dysplasia, increased blasts, cytogenetic abnormalities, or acquired genetic/molecular abnormalities associated with malignancy (**Box 45-3**).[6,45] Morphologically, the marrow features may also overlap with those seen in immune thrombocytopenic purpura (ITP). Germline mutations in *RUNX1, ANKRD26,* or *ETV6* should be considered in patients evaluated for isolated thrombocytopenia with evidence of dysmegakaryopoiesis, particularly if there is a family history of thrombocytopenia or MDS/AML.

Myeloid or Lymphoid Neoplasms With Germline *RUNX1* Mutation

Germline mutations in *RUNX1* (previously known as *CBFA2* or *AML1*) were discovered in patients with FPD with propensity to develop acute myeloid leukemia in 1999.[3] The syndrome is characterized by lifelong thrombocytopenia with increased risk of developing myeloid malignancies and, less frequently, lymphoid malignancy. Platelet studies show normal size with impaired platelet aggregation to epinephrine and collagen, and dense granule storage deficiency. A minority of patients may have near-normal platelet counts; however, platelet function is typically abnormal, leading to increased bleeding risk out of proportion to quantitative platelet count. The overall risk of developing myeloid malignancies is

estimated at 30% to 40% with a median age of 34, with a wide age range of 6 to 72 years.[49] The most common malignancies are myeloid including MDS, AML, and chronic myelomonocytic leukemia (CMML), and often show somatic mutations in the second *RUNX1* allele.[50] T lymphoblastic leukemia (T-ALL) is also reported less frequently, and B lymphoblastic leukemia (B-ALL) or other B-lineage neoplasms are rare.

RUNX1 encodes a subunit of core binding transcription factor that is a regulator of hematopoiesis. It is the most commonly targeted gene in chromosomal translocations in sporadic acute leukemia. *RUNX1* is located on chromosome 21q22 and has been shown to be critical for megakaryopoiesis and proplatelet formation.[46] The germline mutations are heterozygous (monoallelic) with an autosomal dominant inheritance pattern. Mutations comprise missense, frameshift, nonsense, deletions, intragenic duplications, or rearrangements and can occur throughout the gene. The prevalence of germline *RUNX1* mutations has not been determined. The penetrance is incomplete with variable expressivity. Cases of donor-derived leukemia have been reported in patients undergoing stem cell transplantation using a healthy related donor who unknowingly carries the same germline *RUNX1* mutation as the recipient.[11]

Typical baseline bone marrow findings in *RUNX1* patients with isolated thrombocytopenia include normocellular or hypocellular marrow for age with evidence of occasional atypical megakaryocytes or frank dysmegakaryopoiesis. The number of megakaryocytes may be normal or slightly increased with small hypolobated forms or forms with separated nuclear lobes (**Fig. 45-2**). Morphologically, the marrow features may overlap with those seen in ITP. A subset of

RUNX1 patients is misdiagnosed with ITP or "familial ITP" prior to the discovery of germline *RUNX1* mutation. Alternatively, some patients who are stable with isolated thrombocytopenia have been misdiagnosed with MDS solely on the basis of dysmegakaryopoiesis. Dysmegakaryopoiesis is a fundamental feature in RUNX1-FPD that is seen even in asymptomatic family members with the mutation, and should not be considered as a criterion for MDS in the absence of other findings supporting a diagnosis of MDS.[6,45] Marrows may also show a mild increase in eosinophils, which may be related to increased incidence of allergies and atopic symptoms in *RUNX1* patients. As noted, progression to MDS, AML, or CMML is associated with hypercellularity in the setting of new cytopenias, increased blasts, multilineage dysplasia, or cytogenetic/molecular abnormalities (**Fig. 45-3**). The blasts in AML cases typically are with or without maturation demonstrating myeloid immunophenotype, and often contain Auer rods.

Myeloid Neoplasms With Germline *ANKRD26* Mutation

Germline mutations in *ANKRD26* (chromosome 10p12.1) were identified in multiple families with familial thrombocytopenia 2 (THC2) in 2011.[51,52] THC2 is characterized by moderate thrombocytopenia with normal-sized platelets with reduced alpha granules, and absent or mild bleeding. No consistent defect is seen on platelet aggregation studies. The mutations are heterozygous and have an autosomal dominant inheritance pattern. Germline mutations in *ANKRD26* are located in the 5′ untranslated region. These mutations disrupt binding of corepressors RUNX1 and FLI1 to

the promoter and lead to increased *ANKRD26* transcription. The mutations are gain-of-function, resulting in increased signaling in the MPL pathway, impairing proplatelet formation.[14] *ANKRD26* mutations may be missed on standard whole exome sequencing or on NGS panels that do not cover the noncoding 5′UTR. Currently the prevalence of *ANKRD26* germline mutations is unknown. The risk of developing MDS/AML is estimated to be about 24 times greater than expected in the general population. The onset of MDS/AML ranges from 35 to 70 years of age.[53] Other reported HM include CMML, CML, and CLL. Similar to RUNX1-FPD, dysmegakaryopoiesis is common in the bone marrow in patients with stable disease and without malignancy.[48] The development of MDS/AML is associated with additional cytopenia/cytoses, multilineage dysplasia, increased blasts, and acquired cytogenetic/molecular abnormalities.

Myeloid or Lymphoid Neoplasms With Germline *ETV6* Mutation

ETV6 is located on chromosome 12p13. It is a member of the ETS family of transcription factors and is a transcriptional repressor. *ETV6* is targeted in chromosomal translocations with over 30 partners in sporadic acute myeloid and lymphoblastic leukemia. In 2015, several families with thrombocytopenia and increased hematologic neoplasms were found to have germline mutations in *ETV6*.[54,55] Both myeloid and lymphoid malignancies were reported, including B lymphoblastic leukemia (most common), MDS, AML, CMML, and myeloma. Other cancers were also reported, including breast cancer and colorectal carcinoma. Currently, the prevalence of germline *ETV6* mutations is undefined. A hematologic malignancy

has been diagnosed in approximately 30% of all reported carriers. Patients have mild to moderate thrombocytopenia, with normal platelet size, and mild to moderate bleeding tendency. Germline mutations typically involve the ETS DNA binding domain, resulting in impaired nuclear localization and reduced transcriptional repression by ETV6 leading to decreased proplatelet formation. Increased small hypolobated immature megakaryocytes are typically seen in the marrow with decreased mature forms (**Fig. 45-4**). There may also be prominent dyserythropoiesis.

Hematologic Neoplasms with Germline Predisposition Associated with A Constitutional Disorder Affecting Multiple Organ Systems

Myeloid Neoplasms With Germline *GATA2* Mutation

Germline heterozygous mutations in *GATA2* were first reported in 2011 by multiple groups that described four overlapping syndromes, each of which was associated with development of myeloid malignancies. The four syndromes were:

- **MonoMac syndrome** characterized by monocytopenia, severe immunodeficiency with *Mycobacterium avium* complex (MAC) infections, human papillomavirus (HPV), and other viral infections; pulmonary alveolar proteinosis; and hypoplastic MDS and CMML[56-58]
- **Dendritic cell, monocyte, and lymphocyte (DCML) deficiency**, characterized by low monocytes,

dendritic cells, B cells, and natural killer (NK) cells with opportunistic infections and high incidence of MDS[59,60]

- **Familial MDS/AML** families with increased incidence of MDS and AML[61]
- **Emberger syndrome** characterized by lymphedema, sensorineural deafness, warts, and MDS[62,63]

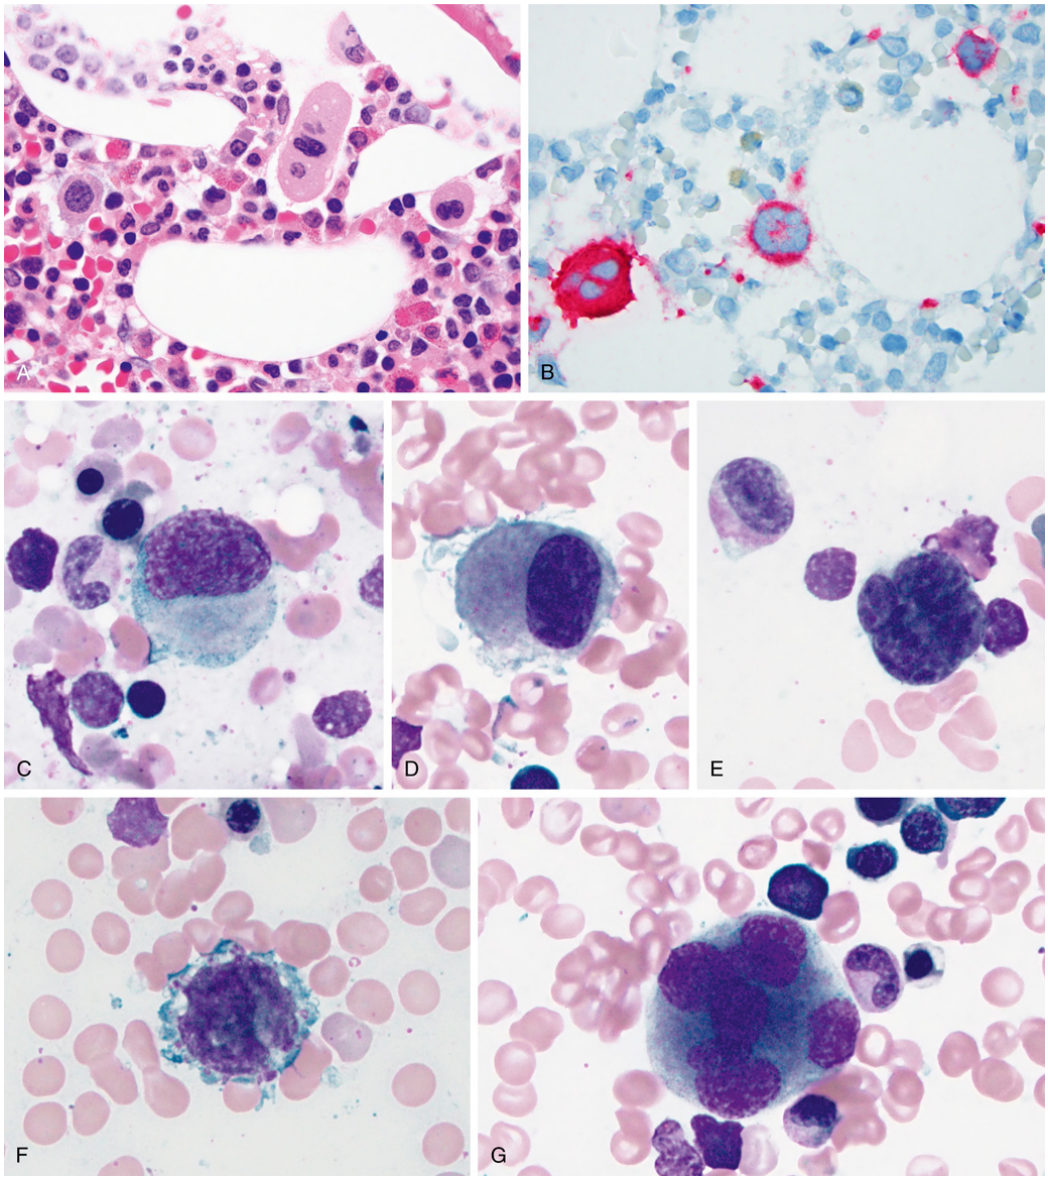

FIGURE 45-2 Dysmegakaryopoiesis in RUNX1 familial platelet disorder in the absence of myelodysplastic syndrome (MDS) or myeloid malignancy.**A,** Normocellular marrow with dysmegakaryopoiesis (small monolobated or hypolobated megakaryocytes, and megakaryocytes with separated nuclear lobes) from a female in her 4th decade with a lifelong

history of stable isolated thrombocytopenia and germline *RUNX1* mutation. There were no additional cytopenias or cytoses. Myelopoiesis and erythropoiesis were normal and there was no increase in blasts. Cytogenetics revealed a normal karyotype. Next-generation sequencing (NGS) myeloid mutation analysis revealed only the known germline *RUNX1* mutation. **B,** CD61 stain demonstrated abnormal small hypolobated megakaryocytes. **C–G,** Typical baseline abnormal megakaryocytes often seen on aspirate smears of stable pediatric and adult RUNX1 FPD patients with isolated thrombocytopenia and no additional evidence of myelodysplasia. The abnormal megakaryocytes include small mononuclear forms, forms resembling micromegakaryocytes, naked megakaryocyte nuclei, and forms with separated nuclear lobes. The baseline abnormal megakaryocytes may represent over 10% of the megakaryocytes in the marrow; however, this finding should not be used as a criterion for myelodysplasia. The development of MDS is associated with multilineage dysplasia, additional cytopenia other than thrombocytopenia, increased blasts, or MDS defining genetic abnormalities.

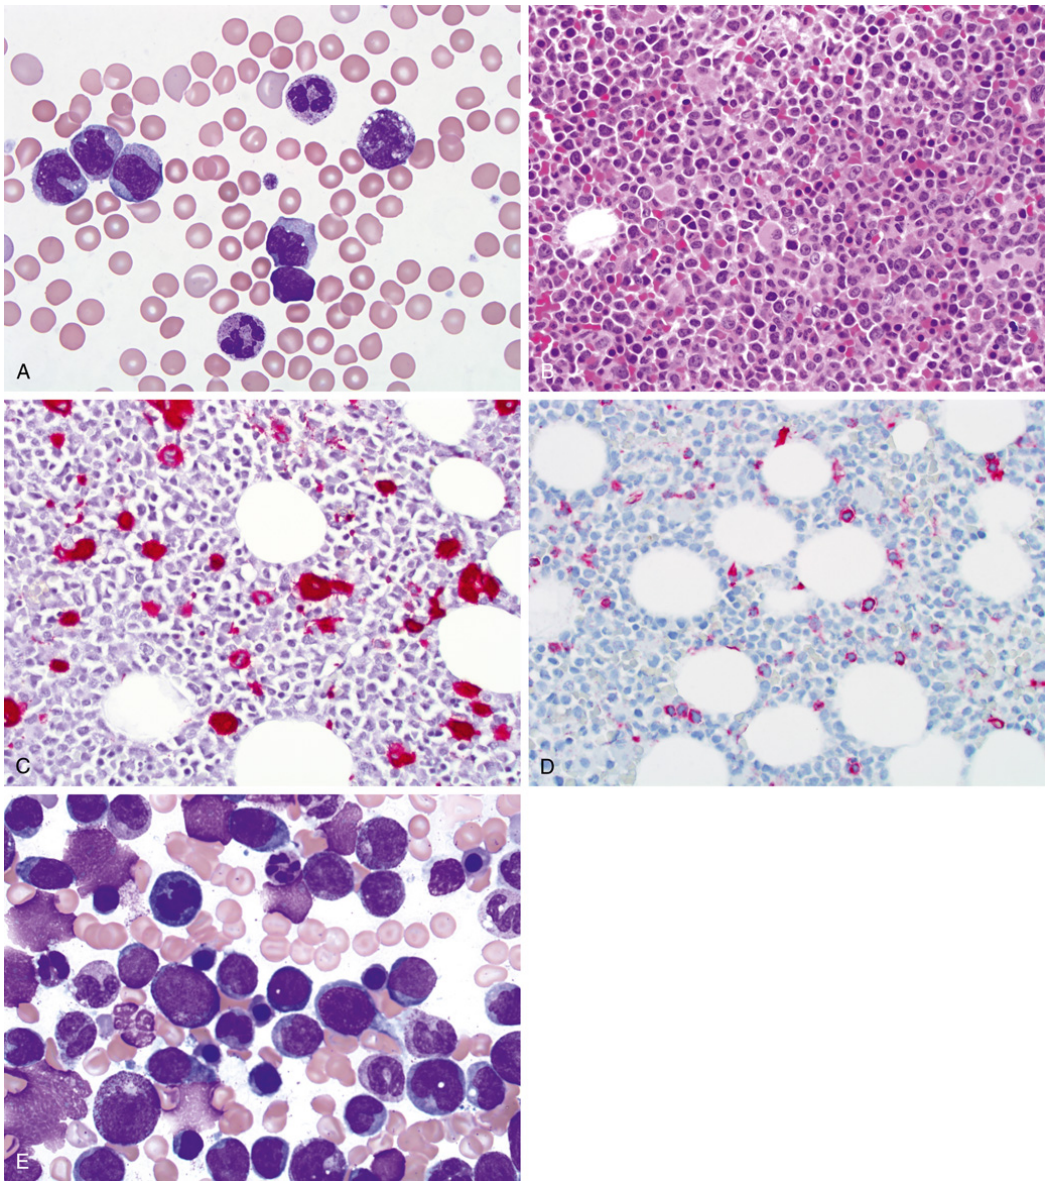

FIGURE 45-3 RUNX1 FPD and development of myeloid malignancy: chronic myelomonocytic leukemia with germline *RUNX1* mutation.Images from the peripheral blood and marrow of a woman in her 6th decade with a lifelong history of thrombocytopenia, confirmed germline mutation in *RUNX1,* and a more recent diagnosis of myelodysplastic syndrome (MDS) with 5q– in

the past several years. At presentation in our institution her white blood cell count (WBC) was markedly elevated with a monocytosis over 8 K/mcL. **A,** Peripheral blood smear showing leukocytosis with increased monocytic cells, left-shifted granulocytes, and circulating blasts. Flow cytometry analysis showed 8% circulating blasts with abnormal myeloid phenotype expressing CD7 *(not shown)*. **B,** Bone marrow core biopsy showing markedly hypercellular marrow with dysplastic megakaryocytes and increased immature precursors. **C,** CD61 highlights frequent small monolobated megakaryocytes. **D,** CD34 stain demonstrates increased blasts. **E,** Aspirate smear showing increased blasts, immature monocytic cells, and left-shifted myeloid cells. Flow cytometry analysis of the marrow aspirate showed 13% blasts, half of which were CD34 positive with an abnormal myeloid phenotype (CD7 positive) and half of which were monoblasts expressing CD64, CD36, HLA-DR++, CD33++, with dim to negative CD14 expression *(not shown)*. Cytogenetic analysis was normal. Next-generation sequencing (NGS) myeloid panel showed presence of the known *RUNX1* germline mutation and additional new mutations in *NRAS, PHF6,* and *BCOR*.

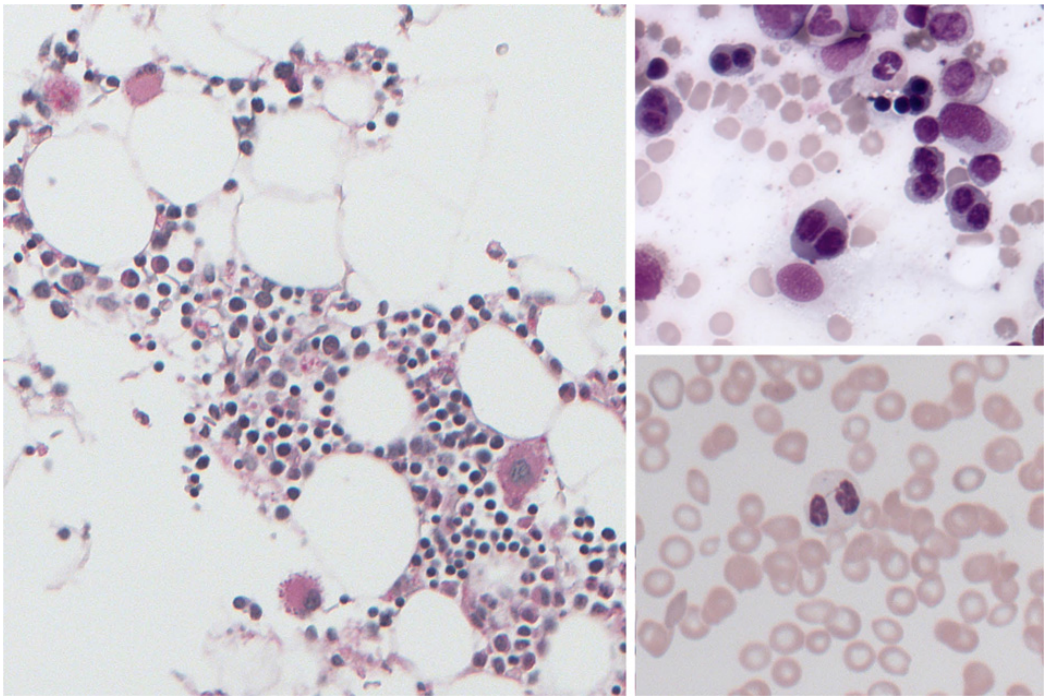

FIGURE 45-4 Refractory cytopenia of childhood (RCC; ICC) with germline *ETV6* mutation.*Left panel,* hypocellular marrow from a 9-year-old female with thrombocytopenia and easy bruising since infancy. Bone marrow was markedly hypocellular for age with dysmegakaryopoiesis composed of multiple hypolobated megakaryocytes. *Top right,* dyserythropoiesis was evident on the bone marrow aspirate smear with frequent binucleated erythroid precursors. *Bottom right,* peripheral smear showed pelgeroid and hypogranular neutrophils. There was no increase in blasts and cytogenetics revealed a normal karyotype. Several years later, in adolescence, the patient developed myelodysplastic syndrome with excess blasts

(MDS-EB) and was transplanted. Other family members were discovered to have thrombocytopenia and germline mutations in *ETV6*. Courtesy of Drs. Akiko Shimamura and Keith Loeb.

The majority of patients initially described were young or middle-aged adults, with some pediatric representation. Subsequently, a large study of pediatric MDS found germline *GATA2* mutations present in up to 7% of pediatric MDS overall, 37% of pediatric MDS with monosomy 7, and in 75% of adolescents with MDS and monosomy 7.[64] *GATA2* is now recognized as one of the most common germline-mutated genes in pediatric MDS. Approximately two-thirds of the pediatric cases harbor de novo mutations not present in either parent. *GATA2* germline mutations have also been reported in cases of congenital neutropenia, bone marrow failure, and aplastic anemia.[65,66] All disorders with germline *GATA2* mutations have overlapping features and are now known as a single genetic disorder with protean manifestations termed *GATA2 deficiency*.[67,68]

GATA2 is a zinc finger transcription factor that regulates hematopoiesis and is critical for stem cell renewal. Germline mutations in *GATA2* are heterozygous with autosomal dominant inheritance. The mutations lead to loss of function and haploinsufficiency. The mutations are classified as missense, null, and regulatory. More recently, synonymous mutations have been reported.[69] Most mutations involve coding regions affecting one of the two the zinc finger domains; however, importantly a minority of patients may have mutations in an intronic region containing an

enhancer element that will not be detected on standard whole exome sequencing[13] or NGS panels that do not cover this region. Ideally, *GATA2* deficiency is diagnosed by full gene sequencing on non-hematopoietic tissue (e.g., cultured fibroblasts from skin biopsy). However, many cases have been picked up by routine NGS targeted-sequencing panels performed on bone marrow or peripheral blood showing pathogenic *GATA2* mutations with high VAFs that undergo subsequent germline confirmation.

The penetrance and expressivity of germline *GATA2* mutations is variable and may be different among family members harboring the same germline mutation. A subset of GATA2 patients present with severe immunodeficiency characterized by markedly decreased monocytes, dendritic cells, B cells, and NK cells. Though a minority have CD4 T-cell lymphopenia, the majority show preservation of T-cell populations, with or without increased large granular lymphocytes or NK/T-cells. Cases with clonal T-cell LGL populations are reported.[67] Opportunistic infections by nontuberculous mycobacteria, fungal organisms, and viral pathogens are not uncommon. HPV infections can lead to severe genital warts, disseminated warts, cervical dysplasia, and squamous cell carcinomas of the genital/anal region[70] in both females and males. Epstein-Barr virus (EBV) may cause severe primary infection and EBV-associated cancers.[71] Though immunodeficiency is marked in many cases, this phenotype is variable and some GATA2 patients have only mildly decreased immune populations, or no evidence of immunodeficiency at all. Other manifestations may include lymphedema, sensorineural deafness, pulmonary alveolar proteinosis, deep vein thrombosis, and miscarriage.

The most common malignancies in GATA2 deficiency are myeloid and include refractory cytopenia of childhood (RCC) in pediatric patients, MDS, AML, CMML, and MDS/MPN. The overall lifetime risk of myeloid malignancy in GATA2 deficiency has been estimated at 70%.[68] The age of onset of myeloid malignancy is highly variable ranging from 5 months to 78 years, with a median onset ranging from 12 to 35.5 years, depending on the study.[68] In some patients, the development of immunodeficiency precedes the development of myeloid malignancy.[72] However, other patients present with myeloid malignancy without recognition of a preceding immunodeficiency.[61] Progressive BMF with features resembling aplastic anemia can also precede progression to MDS or AML (**Fig. 45-5**). Solid tumors have also been reported in GATA2 deficiency.[67] Other hematologic malignancies including B lymphoblastic leukemia and T lymphoblastic leukemia have been rarely described.[73,74]

Bone marrow histologic patterns in GATA2 deficiency demonstrate a range pathology.[75] Common patterns include (1) acute myeloid leukemia in a hypercellular or hypocellular marrow; (2) frank hypoplastic MDS with multilineage dysplasia with or without increased blasts (**Fig. 45-6**); (3) RCC in pediatric patients; (4) hypocellular marrow with mildly dysplastic features approaching but not reaching 10% of cells within lineages, no increase in blasts, and not meeting formal morphologic criteria for MDS called GATA2 bone marrow and immunodeficiency disorder (G2BMID)[76]; or (5) a severely hypocellular marrow resembling aplastic anemia with too few cells to evaluate for dysplastic features (**Fig. 45-5A**). Some patients may present with disseminated MAC in the bone marrow with or without MDS (**Fig. 45-7**). Bone marrow flow cytometry

analysis may be helpful in demonstrating disproportionate loss of monocytes, dendritic cells, B-cell precursors, mature B-cells, or NK-cells indicative of underlying immunodeficiency (**Fig. 45-8**), which is typically not seen in aplastic anemia, or sporadic MDS to the degree seen in GATA2 deficiency.[77] Flow cytometry can also be helpful in evaluating dysplastic immunophenotypic changes. MDS in GATA2 deficiency commonly shows multilineage dysplasia. Rarely one may see marked cellular depletion with serous fat atrophy or prominent fibrosis (**Fig. 45-9**), usually in the setting of pancytopenia without leukoerythroblastosis, and often with clonal cytogenetic abnormalities, and absence of mutations in *JAK2, MPL,* or *CALR*. Dysmegakaryopoiesis is present in nearly all cases often with osteoclast-like megakaryocytes displaying separated nuclear lobes (**Fig. 45-6A**) or micromegakaryocytes (**Fig. 45-5F**), which can be highlighted by CD61 on core biopsies (**Fig. 45-5D**).[58] Myeloid cells often show hypogranularity with abnormal granulation patterns and hyposegmentation (**Fig. 45-6B**). Frequently, the M:E ratio is inverted, with erythroid predominance. Increased blasts (less than 20%) may or may not be present. Despite reduction or loss of B cells and B-cell precursors in many patients, plasma cells are usually present and may aberrantly express CD56. Likewise, despite the loss of monocytes in many patients, macrophages and histiocytes are readily identified.

The most common cytogenetic abnormalities detected in GATA2 deficiency are monosomy 7, trisomy 8, and unbalanced translocation der(1;7)(q10;p10), which support a diagnosis of MDS.[78] The genetic landscape of MDS in GATA2 deficiency differs from that in de novo MDS. The most common acquired mutations include *ASXL1, STAG2,*

DNMT3A, and *SETBP1*.[76,79,80] *SF3B1* mutations are notably uncommon, as are ring sideroblasts, in contrast to de novo adult MDS.

Cytopenic patients with hypocellular marrows need to be carefully followed as transformation to AML can occur suddenly.[81] Transformation to AML or CMML may be accompanied by increased cellularity in the marrow. A subset of patients present with AML without clinical recognition of syndromic features. AML blasts often demonstrate a myeloid immunophenotype (CD34+, CD117+, CD13+, CD33+, CD64–) but can show evidence of monocytic/monoblastic differentiation (CD34–, CD33 bright+, CD64+, CD14 partial + or –). GATA2 patients may present with CMML or MDS/MPN.[82] CMML may occur after the emergence of malignant monocytes after years of monocytopenia.[67]

HSCT can be curative, not only for myeloid malignancy but also for manifestations related to immunodeficiency.[70,83,84] Some family members with the mutation may be asymptomatic and have normal blood counts throughout life. All potential related donors must be screened for *GATA2* mutation to prevent donor-derived MDS/AML, which has developed when healthy mutation-positive donors were inadvertently used as HSCT donors.[8]

Myeloid Neoplasms With Germline *SAMD9* or *SAMD9L* Mutation

In 2016, a syndrome called MIRAGE was reported that was associated with germline mutations in *SAMD9* and characterized by **m**yelodysplasia with monosomy 7, **i**nfection, **r**estriction of growth, **a**drenal hypoplasia, **g**enital phenotypes, and **e**nteropathy.[85] In the

same year, ataxia pancytopenia syndrome was described with germline mutations in a related gene, *SAMD9L,* that was associated with BMF and MDS with monosomy 7.[86] Subsequent studies showed that germline mutations in *SAMD9* and *SAMD9L* are among the most common overall in pediatric MDS in patients without syndromic features of MIRAGE or ataxia pancytopenia syndromes, and in patients suspected of having inherited bone marrow failure.[87,88] *SAMD9L* germline mutations have also been identified in children with severe autoinflammatory disease.[89] *SAMD9* and *SAMD9L* are both located on chromosome 7. Germline mutations are gain-of-function and have antiproliferative effects on hematopoietic cells leading to cytopenia and bone marrow failure. There are multiple compensatory genetic outcomes that are not uncommon in these patients that are either adaptive or maladaptive, representing somatic genetic rescue (SGR).[88] Maladaptive mechanisms to rid cells of the germline mutation include loss of chromosome 7 associated with MDS. Other more adaptive mechanisms include uniparental disomy of chromosome 7q resulting in wild-type *SAMD9* or *SAMD9L* in affected cells, or acquisition of loss-of-function mutations in *cis* to counteract the effect of the germline mutation. In some cases, monosomy 7 may be transient and associated with hematologic remission. Importantly for interpretation of NGS studies, the VAF of *SAMD9* or *SAMD9L* mutations may be lower than expected for germline mutations in hematopoietic cells because of SGR, and may confound the diagnosis. Bone marrow evaluation typically shows a hypocellular marrow with or without dysplastic features (**Fig. 45-10**).

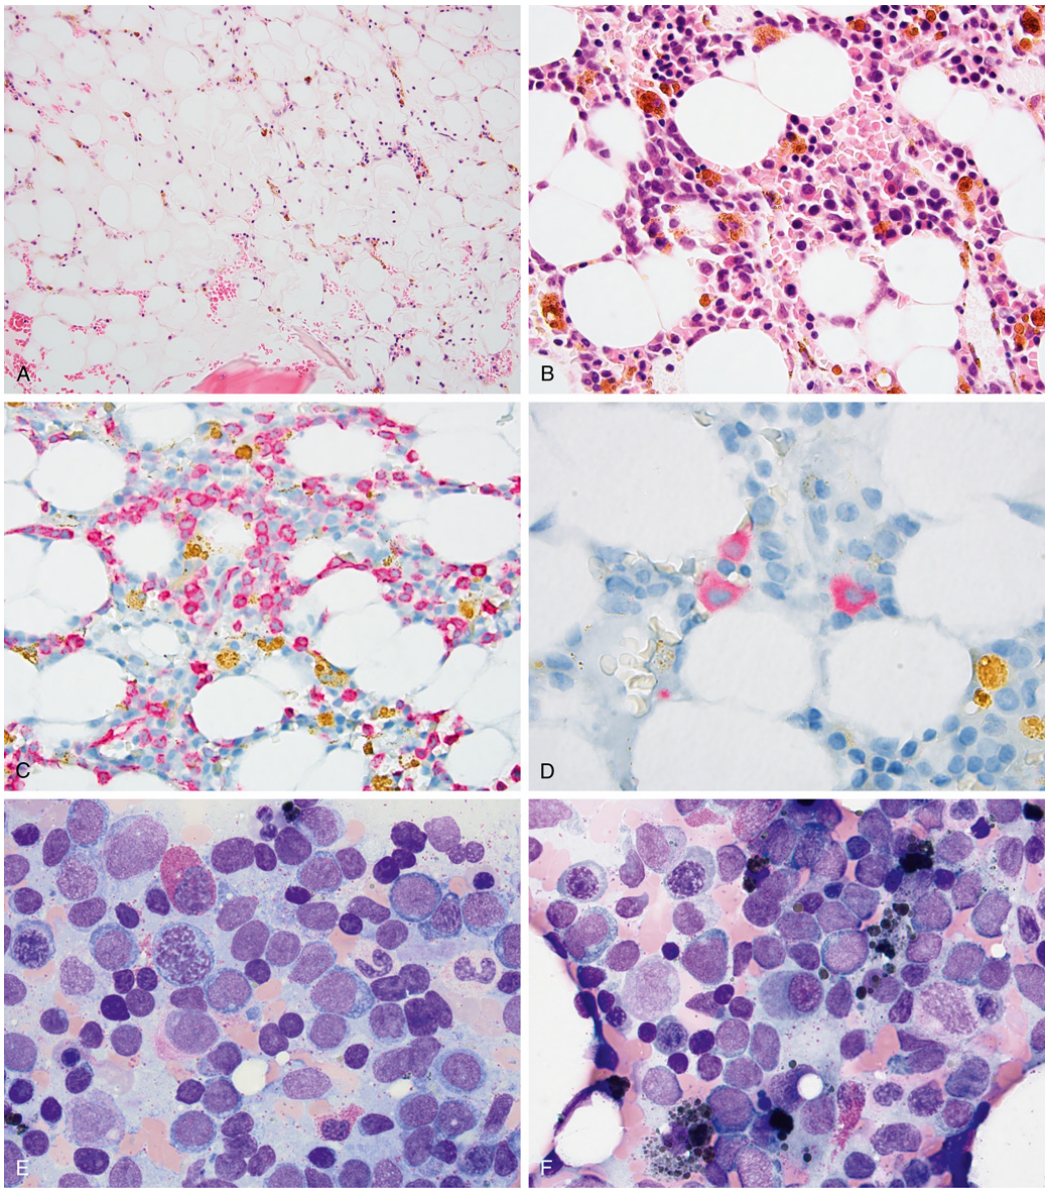

FIGURE 45-5 Acute myeloid leukemia with germline *GATA2* mutation arising in a patient previously diagnosed with aplastic anemia.**A,** Hypocellular marrow with trilineage hypoplasia in a late adolescent male with pancytopenia diagnosed with aplastic anemia (×500). There were areas of serous fat atrophy with a few scattered erythroid precursors and lymphocytes.

No megakaryocytes were seen. The aspirate was paucicellular. There was no increase in blasts and the karyotype was normal. **B,** Three years later in the beginning of his 3rd decade, the bone marrow was hypocellular for age with increased immature precursors, dysplastic megakaryocytes and hemosiderin-laden macrophages (×500). **C,** CD34 showed increased blasts (overall 30%–40%, ×500) that had a myeloid phenotype on flow cytometry analysis *(not shown)*. **D,** CD61 demonstrated very small mononuclear dysplastic megakaryocytes and micromegakaryocytes (×1000). **E,** Bone marrow aspirate smear showed increased blasts with high N:C ratio and dispersed chromatin (×1000). **F,** Micromegakaryocyte with eccentric nucleus in center of field (×1000). Germline *GATA2* mutation was subsequently identified.

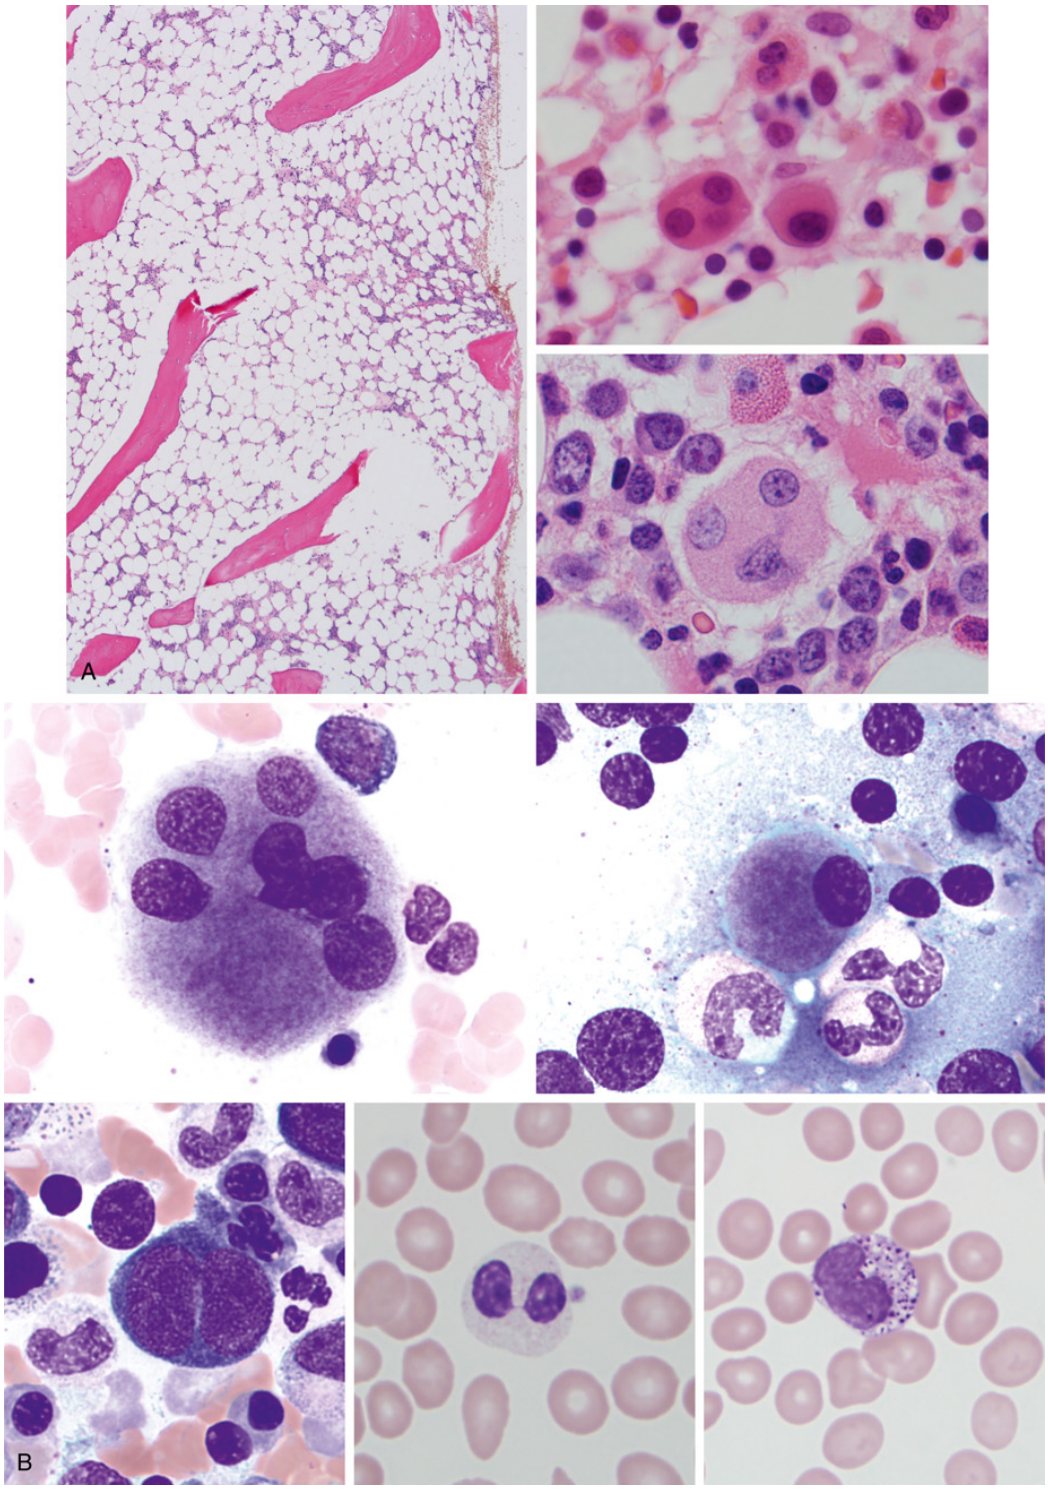

FIGURE 45-6 Hypoplastic MDS with multilineage dysplasia and germline *GATA2* mutation.**A,** Bone marrow is typically markedly

hypocellular for age in a young/middle-aged adult or pediatric patient (*left panel,* ×100), with dysplastic megakaryocytes, including micromegakaryocytes and megakaryocytes with separated nuclear lobes both small and large (*right panels,* ×1000). **B,** Multilineage dysplasia is typically seen on the aspirate smear and peripheral blood (×1000 images). *Upper images:* large megakaryocyte with separated nuclear lobes *(left)* and micromegakaryocyte *(right)*, bone marrow. *Lower images:* dysplastic binucleated erythroid precursor *(left)* bone marrow; dysplastic hyposegmented and hypogranular neutrophil on peripheral smear *(middle)*; and hypogranular basophil on peripheral smear *(right)*.

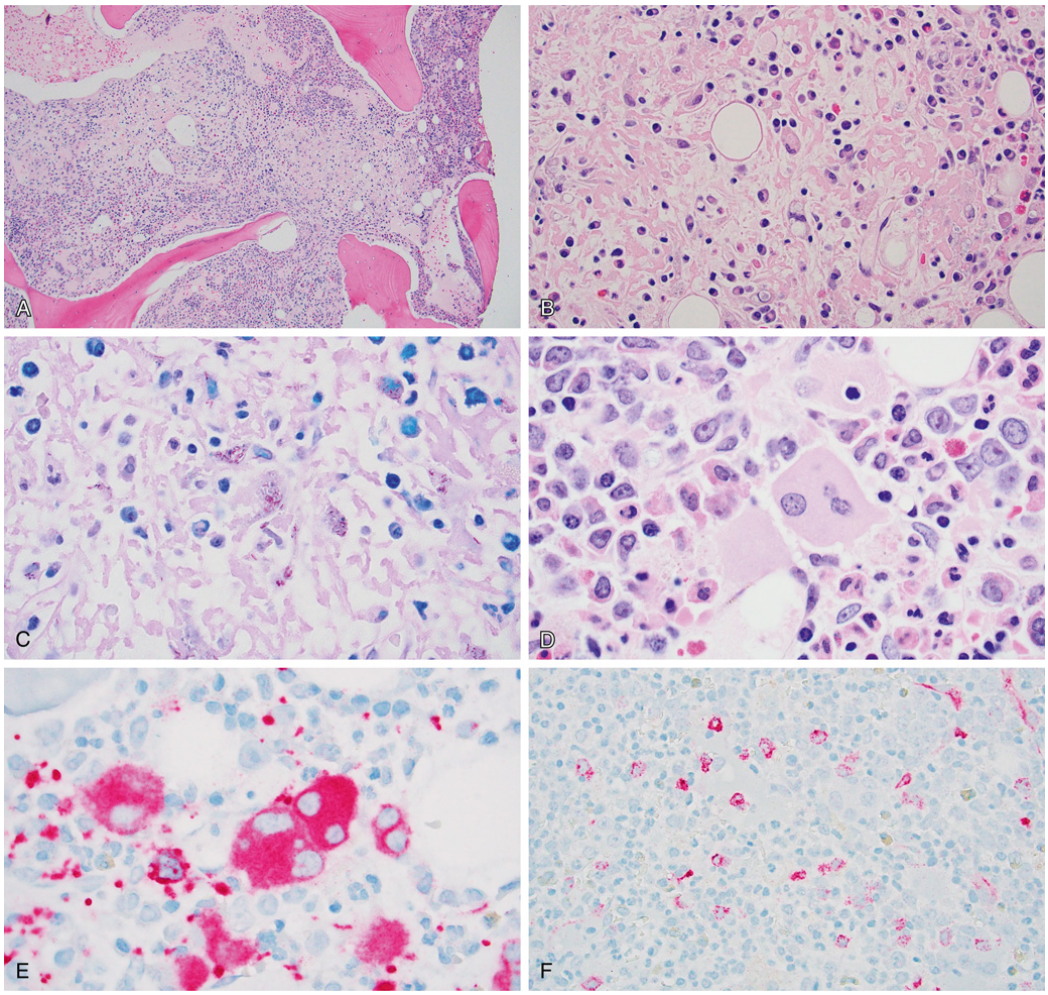

FIGURE 45-7 Bone marrow with coexistent disseminated nontuberculous mycobacterial infection and myelodysplastic syndrome (MDS) with excess blasts with germline *GATA2* mutation.**A,** Bone marrow with prominent granulomatous inflammation (×100) from a woman presenting in her 5th decade with disseminated *Mycobacterium avium* complex (MAC) and aspergillus infection diagnosed with *GATA2* deficiency. **B,** High-power view showing presence of dysplastic megakaryocytes, plasma

cells, and lymphocytes. **C,** Acid-fast bacilli stain demonstrated AFB-positive organisms (×1000). **D,** Dysplastic megakaryocyte with separated nuclear lobes (×1000). **E,** CD61 immunostain highlighting megakaryocytes with separated nuclear lobes and a small mononuclear form. **F,** CD34 immunostain demonstrated increased CD34 positive cells (×500) that were overall 6% to 8% with a myeloid immunophenotype on flow cytometry analysis that also showed near absence of monocytes, plasmacytoid dendritic cells, natural killer (NK) cells, and B-cell precursors *(not shown)*. Cytogenetic analysis revealed an abnormal karyotype with trisomy 8.

Myeloid Neoplasms Associated With Bone Marrow Failure Syndromes

Fanconi Anemia

FA is a heterogeneous genetic disorder with widely variable presentation including congenital anomalies, bone marrow failure, and nonhematologic symptoms.[90] Congenital anomalies may include thumb and radial ray abnormalities, kidney and urinary tract malformations, café-au-lait spots, and short stature. Patients may present at any age including adulthood, though typical age of presentation is between 5 and 10 years of age. Diagnosing FA requires a high index of suspicion owing to the diversity of symptoms and similarities between FA and other syndromes.[91] FA is likely underdiagnosed; it is occasionally recognized in adults who develop

unusual cancers or toxicities upon anticancer treatment. FA is caused by germline mutations in one of multiple FA genes, and mutations may involve any of 23 genes and are mostly autosomal recessive with some rare X-linked recessive or autosomal dominant subtypes. The cumulative incidence of BMF varies from 18% to 83% depending on the risk groups.[92] The cumulative incidence of AML at age 40 years is estimated at 15% to 20%, while the incidence of MDS at age 50 years is 40%.[93] The relative risk of AML is increased 700-fold in comparison with the general population and that of MDS is increased 6000-fold.[94] AML is particularly more frequent in FANCD1/BRCA2 group. Chromosomal aberration involving chromosome 7, including −7/−7q, is significantly correlated with more advanced dysplasia and commonly part of a clone with a more complex karyotype that frequently also shows gain of 3q material.[92] Sequential analysis of clonal progression in FA has revealed that 3q-gains often precede changes involving partial or whole loss of chromosome 7.[92] The emergence of monosomy 7 in FA is associated with poorer prognosis and increased risk of developing MDS and AML.[95] Patients with FA may also present with T-ALL and are also at risk for solid tumors, particularly squamous cell carcinomas of the head, neck, gastrointestinal (GI) tract, vulva, and hepatic tumors. In a family study of FA, heterozygous mutations in *FANCA* or *FANCC* were not associated with increased cancer risk; because of small numbers, other FA genotypes could not be assessed. Microscopic examination of a bone marrow biopsy shows hypoplasia and hypocellularity. Hypocellularity is often out of proportion of cytopenias. In some cases, erythroid hyperplasia and dysplasia are also present. Bone marrow evaluation every year starting in early

childhood is used to screen for early evidence of MDS (**Fig. 45-11**) or AML before clinical symptoms occur. Therapy for AML in FA is challenging given the hypersensitivity of patients' cells to cytotoxic chemotherapeutics used to treat routine de novo AML; reduced-intensity chemotherapy leading to HSCT is recommended.

FIGURE 45-8 Bone marrow flow cytometry analysis may show underlying immunodeficiency in patients with germline *GATA2* mutations and bone marrow failure or myeloid malignancy.Male in his 4th decade with myelodysplastic syndrome (MDS) with multilineage dysplasia and germline *GATA2* mutation. A subset of patients with *GATA2* deficiency *(right panels)* and cytopenias show evidence of disproportionate loss of monocytes (CD14+ and CD33+) **(A)**; plasmacytoid dendritic cells (B, CD123+ and HLA-DR+) **(B)**; B-cell precursors (CD10+ lymphocytes) and mature B-cells (CD20+ and CD10– lymphocytes) **(C)**; natural killer (NK) cells (CD56+ and CD3– lymphocytes) in the bone marrow **(D)** in comparison to healthy control marrow *(left panels)*.

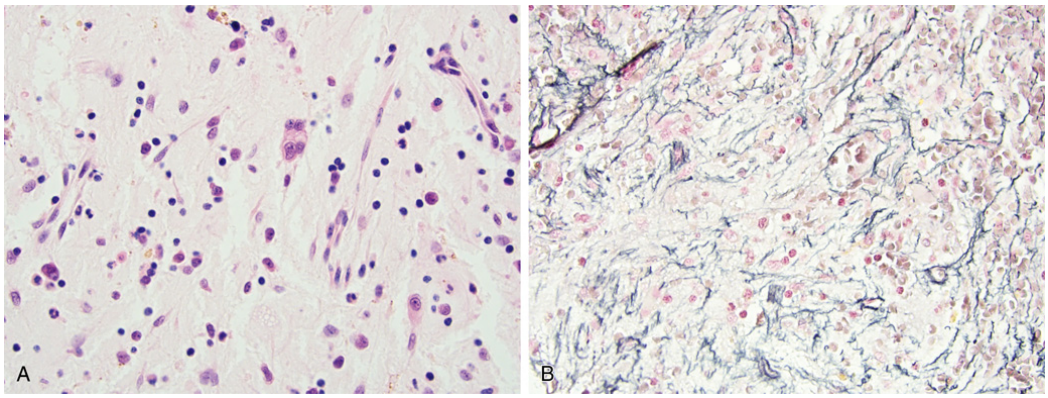

FIGURE 45-9 Pediatric MDS resembling atypical myelofibrosis in GATA2 deficiency.Bone marrow from pediatric male in first decade of life with history of pancytopenia, warts, and respiratory infections. Family history was significant for a sibling with MDS. **A,** Marrow shows marked cellular depletion in a fibrotic background with a few dysplastic megakaryocytes, scattered lymphocytes, and plasma cells; no increase in blasts. **B,** Reticulin stain showed evidence of reticulin fibrosis. Monosomy 7 detected. Germline *GATA2* mutation identified. The findings were consistent with MDS, not otherwise specified (NOS; ICC) or childhood MDS with low blasts (WHO, 5th ed.), with germline *GATA2* mutation.

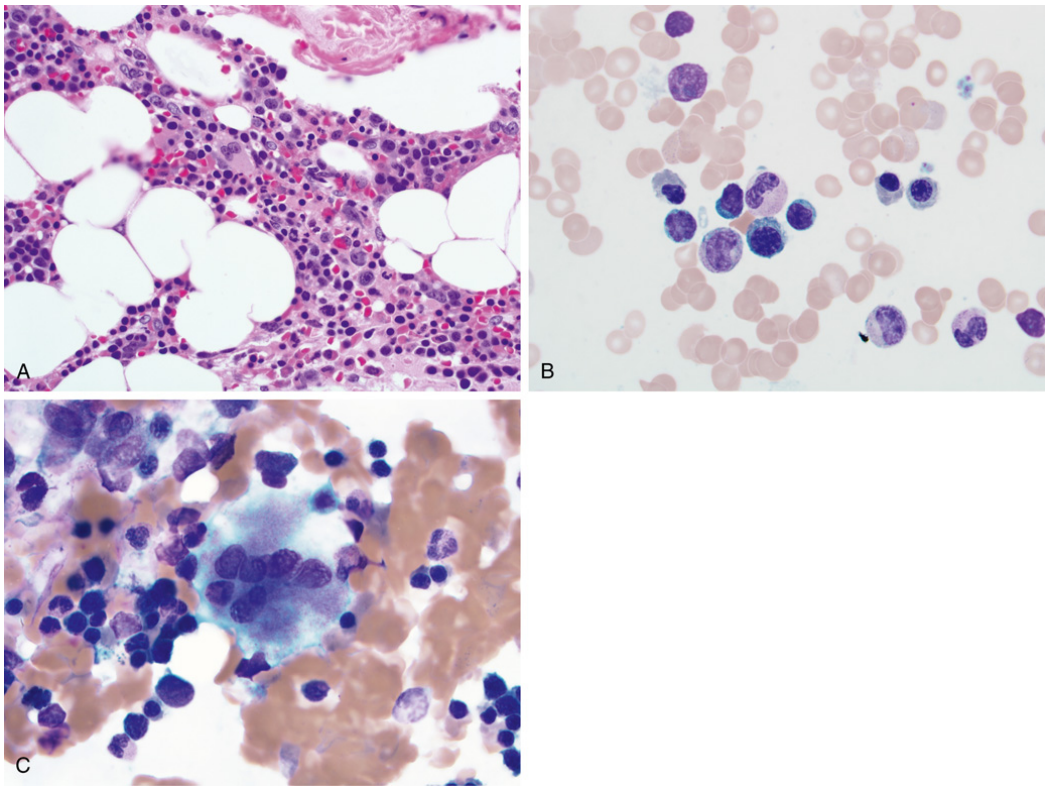

FIGURE 45-10 RCC with germline *SAMD9L* mutation.**A,** Bone marrow core biopsy from a pediatric female in 1st decade of life with an autoinflammatory disorder since birth with fever, rashes, viral infections, and pancytopenia. The marrow was hypocellular for age (×500). **B,** The aspirate smear showed evidence of dyserythropoiesis with nuclear budding in a subset of erythroid precursors (×1000). **C,** Dysplastic megakaryocyte on aspirate smear (×1000). There was no increase in blasts. Cytogenetic analysis showed an abnormal karyotype with monosomy 7 and the patient was diagnosed with refractory cytopenia of childhood (RCC; ICC). A de novo germline mutation in

SAMD9L was identified. Unexpectedly, 6 months later the cytopenias spontaneously improved. The subsequent bone marrow biopsy/aspirate showed no overt evidence of dysplasia and the cytogenetic analysis showed a normal karyotype without monosomy 7. Evaluation of the *SAMD9L* mutation in hematopoietic cells showed evidence of somatic genetic reversion via uniparental disomy of 7q.

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome (SDS) is a multisystem disorder that is characterized by BMF, exocrine pancreatic dysfunction, and predisposition to myeloid malignancies. SDS is caused by biallelic or homozygous variants in the gene *SBDS* encoding Shwachman Bodian-Diamond syndrome protein that account for >90% of cases of SDS.[96] Classically, SDS presents in infancy or early childhood with failure to thrive, steatorrhea, recurrent infections, or growth retardation; nearly all affected children have intermittent or persistent neutropenia at presentation. In a case series that included 129 patients in 116 SDS families who were diagnosed clinically (before the widespread availability of genetic testing), the median age at diagnosis was 1 year (and ranged from 0.1 to 13 years).[97] Although SDS patients typically present with neutropenia as their initial hematologic finding, other cytopenias may present in any lineage either singly or in combination.[98] Cytopenias may be mild or absent; however, patients remain at risk for myeloid malignancies even if cytopenias were previously asymptomatic.[99] At baseline, the

marrow is typically hypocellular even if blood counts are normal. Myeloid dysplasia such as nuclear hyposegmentation and hypogranularity are common, and mild megakaryocytic dysplasia may be present. Erythroid dysplasia is typically absent at baseline.[99]

Clonal cytogenic abnormalities involving i(7q) and del(20q) are reported in patients with SDS but are not associated with progression to malignancy.[100] The risk of worsening cytopenia(s), clonal myeloid evolution, or AML is estimated at 20% and typically occurs by age 18.[101] The Severe Chronic Neutropenia International Registry reported a 1% per year progression rate to MDS/AML in patients with SDS, with a cumulative risk of MDS/AML reaching 36% by 30 years of age.[102] Small stable clones with heterozygous *TP53* mutations are common in patients with SDS; however, biallelic *TP53* mutations were observed in myeloid malignancies and may be present prior to the development of overt malignancy.[103]

Telomere Biology Disorders Including Dyskeratosis Congenita

Dyskeratosis congenita (DC) is an inherited BMF syndrome characterized by abnormal skin pigmentation, nail dystrophy, oral premalignant leukoplakia, BMF, and cancer predisposition, with increased risk for squamous cell carcinoma and hematolymphoid neoplasms. DC and telomere biology disorders (TBD) are a spectrum of disorders caused by pathogenic germline variants in telomere biology genes. Although germline mutations in *DKC1* are classically associated with triad of dysplastic nails, reticular skin pigmentation, and oral leukoplakia, a large subset of patients lack these findings at diagnosis.[104] DC is heterogeneous at the genetic level, depending on

the affected gene and can be inherited in X-linked *(DKC1)*, autosomal dominant *(TERC, TINF2, ZCCHC8, RPA1, NAF1)*, autosomal recessive *(CTC1, NHP2, NOP10, POT1, STN1, WRAP53)*, or both autosomal dominant and autosomal recessive patterns *(PARN, RTEL1, TERT)*.[105] Mutations in at least 16 telomere- and telomerase-associated genes have been linked to DC, although the genetic basis of the disease is still undetectable in approximately 30% to 40% of DC cases.[106] DC is a disease of defective telomere maintenance, and patients with DC have premature telomere shortening and subsequent replicative senescence, leading to premature stem cell exhaustion and tissue failure. The BM findings in DC are variable and range from normal to different severity of aplasia depending on the stage of the disease. Sometimes it is indistinguishable from aplastic anemia caused by other causes.[107] Fetal hemoglobin levels are increased. NCI cohort of 197 DC patients found a cumulative incidence of cancer of 2% by age 50 years for leukemia and 11% by age 50 years for solid cancers.[108] Patients with autosomal dominant mutations in *TERT* or *TERC* may display variable penetrance and present in adulthood with pulmonary fibrosis, hepatic cirrhosis, and early graying of the hair.[109] Bone marrow is typically hypocellular with diminished hematopoietic progenitors (**Fig. 45-12**).[109]

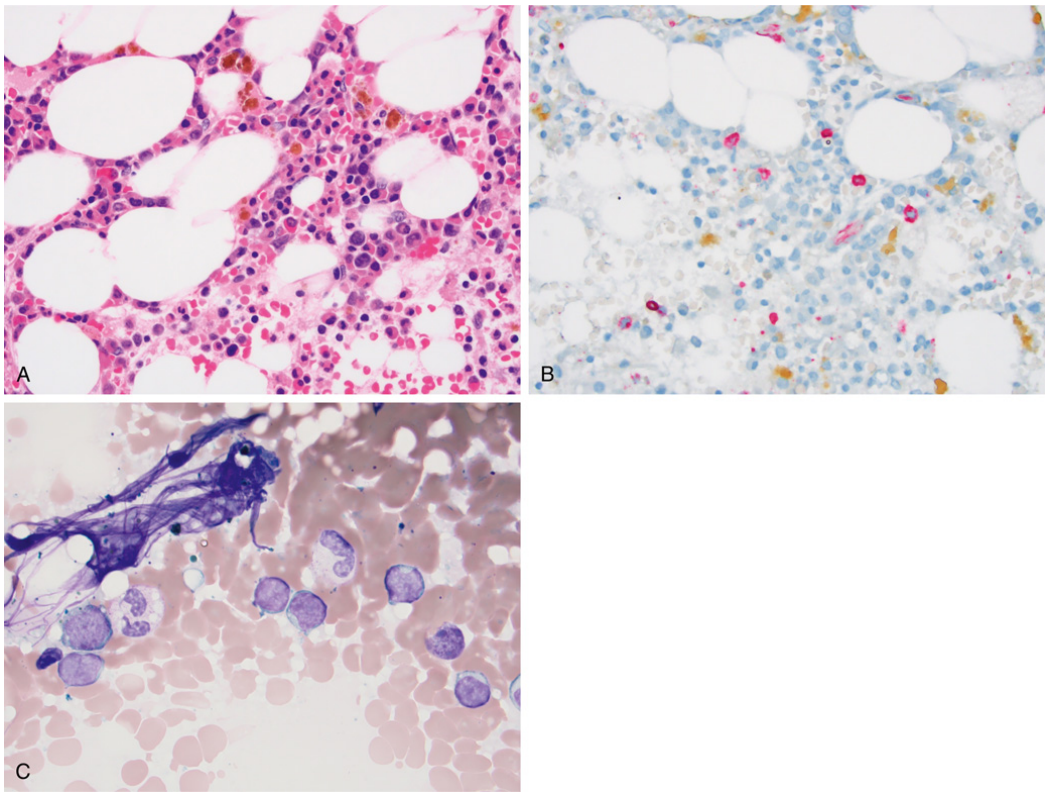

FIGURE 45-11 Refractory cytopenia of childhood (RCC) with monosomy 7 in Fanconi anemia.**A,** Bone marrow from young female in 1st decade of life with history of Fanconi anemia. The marrow is hypocellular for age with trilineage hypoplasia and scattered hemosiderin laden macrophages reflecting history of transfusions. Megakaryocytes were essentially absent confirmed by CD61 stain *(not shown)*. **B,** CD34 immunostain showed few scattered positive cells consistent with blasts that were less than 5%. Flow cytometry analysis demonstrated lack of hematogones suggesting that nearly all the CD34-positive cells were myeloid. **C,** Touch prep of the biopsy showed areas with left-shifted myeloid

cells and blasts. Cytogenetic analysis revealed an abnormal karyotype with monosomy 7 that was not detected on prior analysis.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) is a genetically heterogeneous condition of BMF usually diagnosed in early childhood and characterized by a chronic and severe shortage of neutrophils that manifest early in infancy with absolute neutrophil count (ANC) below 0.5×10^9/L, leading to life-threatening bacterial infections. Patients are highly susceptible to bacterial infections, with infections by *Staphylococcus aureus* and gram-negative bacteria being the most life-threatening. It is now well-established that mutations in autosomal dominant mutations in *ELANE* the gene-encoding neutrophil elastase, as well as *HAX1* and other genes *(CSF3R, GFI1, G6PC3, JAGN1, WAS)*, are the most frequently observed genetic defects in SCN patients. At baseline, the marrow for *ELANE*-mutant SCN is mostly normocellular and classically shows early myeloid maturation arrest at the promyelocyte stage.[110]

Up to 40% of patients with SCN may develop clonal hematopoiesis with acquired mutations in *CSF3R*. These clones may persist for months or even years without progressing to malignancy. Importantly, SCN patients have a high risk of developing MDS or AML, with a median incidence of ~20%, 15 years after initiation of granulocyte colony stimulating factor (GCSF) treatment.[111,112] The majority of SCN patients with leukemic progression show the appearance of hematopoietic clones with somatic mutations in *CSF3R,* resulting in a truncated form of CSF3R with defective

internalization and aberrant signaling properties,[113] and somatic mutations in *RUNX1*.[110]

Diamond Blackfan Anemia

Diamond-Blackfan anemia (DBA) is inherited pure red blood cell aplasia typically caused by pathogenic autosomal dominant variants in genes encoding ribosomal proteins *(RPS19, RPS17, RPS24, RPL35A, RPL5, RPL11, RPS7, RPS26, RPS10)* and is a genetically and clinically heterogeneous disorder characterized by erythroid failure, congenital anomalies, and a predisposition to cancer. The molecular biology of DBA is being extensively explored and, in more than 50% of cases, the syndrome appears to result from haploinsufficiency of either a small or large subunit-associated ribosomal protein.[114] X-linked mutations in GATA1 also cause a DBA phenotype. DBA is often associated with congenital anomalies, particularly abnormalities of the thumbs, facial features, kidneys, heart, and short stature. The classic presentation of DBA includes a usually macrocytic, or occasionally normocytic, anemia with reticulocytopenia, essentially normal neutrophil and platelet counts, and a normocellular bone marrow with a paucity of erythroid precursors in a child younger than 1 year, but patients may present in adulthood.[115] In addition to macrocytosis, the presence of elevated fetal hemoglobin levels (HbF) and an elevation in erythrocyte adenosine deaminase enzyme (eADA) activity are important supporting features associated with DBA. The presence of macrocytosis and elevated HbF, each felt to be a consequence of “stress erythropoiesis” and skipped erythroid cell divisions, is not unique to DBA but is observed in many incidences of BMF. Patients

appear to be at an increased risk of cancer; the two most prevalent solid tumors are colorectal cancer and osteogenic sarcoma.[116] There is also some increased risk of myeloid malignancy.[117] The bone marrow is usually normocellular or slightly hypocellular and shows a characteristic of erythroblastopenia with normal granulocytic and megakaryocytic lineages.[118]

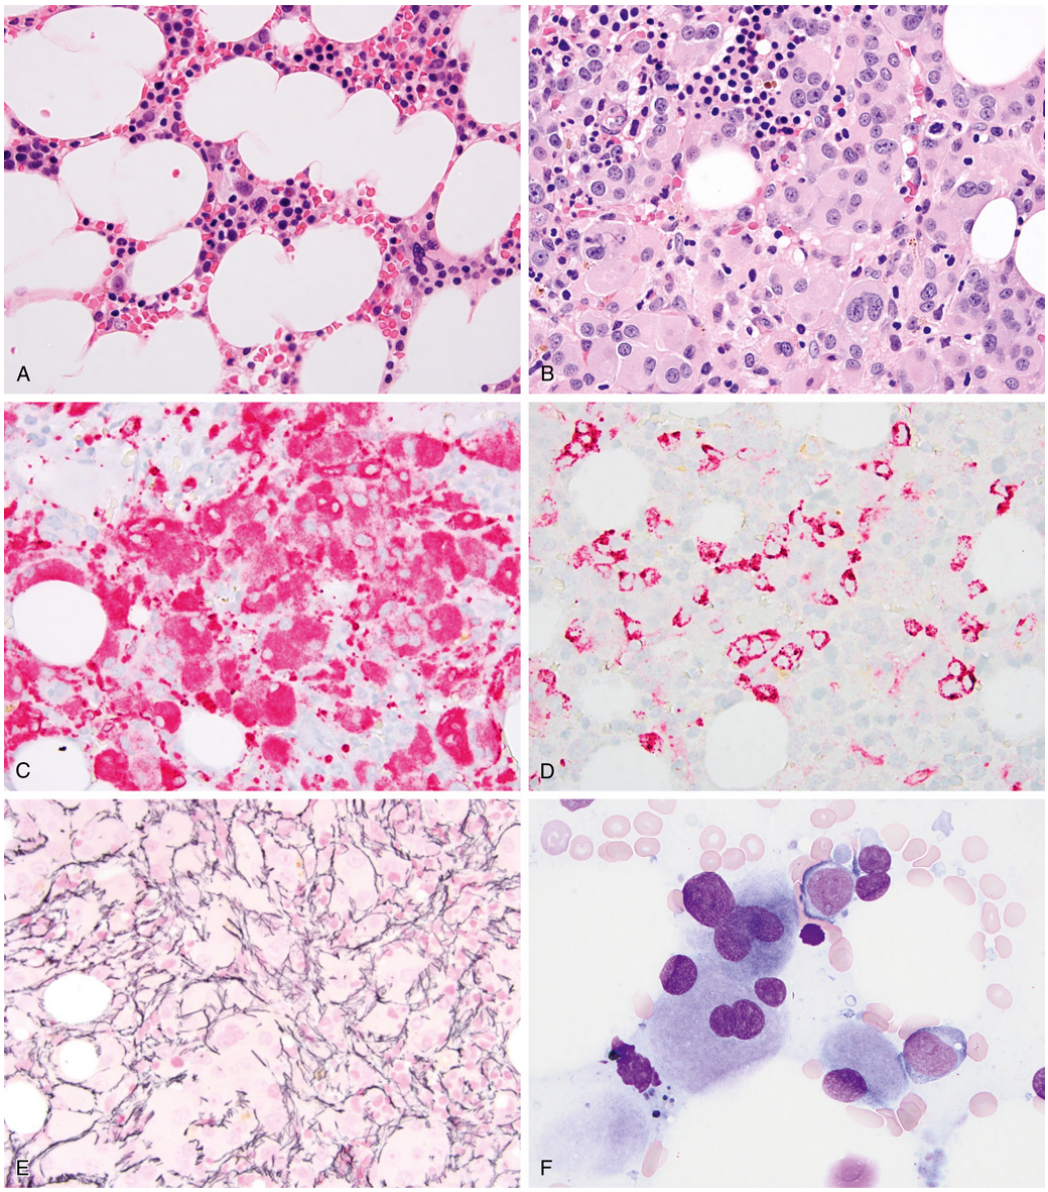

FIGURE 45-12 Myelodysplastic syndrome (MDS)/acute myeloid leukemia (AML; ICC) with germline *TERT* mutation arising in a patient with prior history of aplastic anemia.**A,** Bone marrow core biopsy from a male in his 6th decade with a history of pulmonary fibrosis, early graying of the hair, and moderate pancytopenia. The biopsy showed a hypocellular marrow for age with

decreased trilineage hematopoiesis with a few small hypolobated megakaryocytes, but without overt dysplasia in more than 10% of cells in any lineage, and no increase in blasts (×500). Cytogenetic analysis revealed a normal karyotype, and the patient was diagnosed with moderately severe aplastic anemia. Flow fluorescence in situ hybridization (FISH) showed very short telomeres. Genetic studies identified a germline *TERT* mutation. **B,** Six years later, there was a significant drop in the patient's peripheral blood counts. Bone marrow biopsy showed a markedly hypercellular marrow with sheets of dysplastic megakaryocytes (×500). **C,** Dysplastic megakaryocytes highlighted by CD61 immunostain. **D,** CD34-stained increased blasts with clustering overall 15% to 19%. The blasts were of myeloid on flow cytometric analysis *(not shown)*. **E,** Reticulin stain showing marked reticulin fibrosis in the areas of dysplastic megakaryocytes. **F,** Aspirate smear showing dysplastic megakaryocytes and a few blasts (×1000). Cytogenetic analysis showed trisomy 8 and duplication of 1q MDS/AML (ICC).

Juvenile Myelomonocytic Leukemia Associated With Neurofibromatosis, Noonan Syndrome, or Noonan-Syndrome-Like Disorders (CBL-Syndrome)

JMML is an MDS/myeloproliferative neoplasm (MPN) overlap syndrome of the pediatric age group characterized by sustained, abnormal, and excessive production of myeloid progenitors and monocytes, aggressive clinical course, and poor outcomes. JMML accounts for 1% of all pediatric leukemias, with an incidence of about 1.2 cases per million persons per year.[119] The median age at which it is diagnosed is 2 years old, and about three-fourths of cases are diagnosed before 3 years of age; by 6 years, 95% of cases are detected. Patients present with splenomegaly, hepatomegaly, lymphadenopathy, enlarged tonsils, interstitial lung disease, and gut infiltrates. About one-quarter of patients have leukemic skin lesions. The common molecular denominator of JMML is the deregulation of the intracellular RAS signal transduction pathway, caused in >90% of cases by mutations in one (or, rarely, more than one) of five primordial genes (*PTPN11, NRAS, KRAS, NF1,* or *CBL*).[120] Karyotype abnormalities and additional epigenetic alterations can also be found in JMML. Neoplasms in children resembling JMML without RAS-pathway mutations are classified as JMML-like in the ICC.[5,6]

Two congenital developmental disorders predispose to JMML: Neurofibromatosis type 1 (NF1) and Casitas B-lineage lymphoma (CBL) syndrome caused by monoallelic loss-of-function mutation of the *NF1* or *CBL* gene, which may have been inherited or arisen de novo.[121,122] JMML develops after somatic biallelic inactivation of the respective gene in hematopoietic progenitor cells, predominantly by mitotic gene recombination resulting in uniparental isodisomy.[123,124] Overall, 10% to 15% of JMML cases are driven by *NF1,* and indicative features in children with JMML/NF1 include

presence of ≥6 cutaneous café-au-lait spots or family history, neurofibromas, optic pathway gliomas, bone lesions, and neurologic abnormalities.[125] NF1 functions as a Ras-GAP and thus negatively regulates the RAS pathway.[126] CBL is a E3 ubiquitin ligase mediating the decay of receptor tyrosine kinases in the RAS pathway. Mutations targeting exons 8 or 9 account for ~15% of JMML cases.[127] CBL syndrome, a Noonan-like RASopathy, has a wide phenotypic spectrum and presenting features including impaired growth, facial anomalies, developmental delay, cryptorchidism, autoimmune phenomena, and notably, neurovasculitis.[124]

Noonan syndrome (NS) has an incidence of 1 in 1000 to 2500 children; patients with NS exhibit a short statue, facial dysmorphism, congenital heart defects, skeletal defects, a webbed neck, mental retardation, and cryptorchidism.[128] The genetic basis is a germline mutation in *PTPN11* (around 50% of NS cases), and other members of the RAS pathway include *SOS1, RAF1, KRAS, BRAF,* and *NRAS*.[129] Children with NS may experience a transient myeloproliferative disorder (MPD) at a very young age, although the condition is indistinguishable from JMML by clinical and hematologic features.[130] There is an overlap in the landscape of *PTPN11* mutations between JMML and NS/MPD, and it is not well understood how the same mutation elicits a transient disorder when present in the germline and a fatal disorder when acquired somatically. The occurrence of germline and somatic RAS pathway mutations in the same clinical context requires analysis of nonhematopoietic to differentiate these conditions.

Diagnostic criteria for JMML is listed in **Chapter 48**. Leukocytosis is usually present, but occasionally, the WBC is within

the normal range.[131] There is monocytosis, often with dysplastic forms, and a monocyte counttypically >1 × 10^9/L. Presence of myeloid and often erythroid precursors is a consistent feature of JMML. Thrombocytopenia is often present with the exception of cases of NF1-associated JMML, who mostly have platelet counts within the normal range.[131] The bone marrow is hypercellular with myeloid cell predominance and reduced megakaryocytes, and the monocytic compartment is generally less prominent than in peripheral blood. The blast percentage must be less than 20%.

Myeloid or Lymphoid Neoplasms Associated With Down Syndrome

Down syndrome (DS) is the most common chromosomal abnormality among live-born infants. DS manifests as a developmental delay with a characteristic spectrum of congenital malformations, which may include the heart, gastrointestinal, musculoskeletal, and complications in other organ systems. Hematologic abnormalities are common in children with DS. Among other hematologic disorders, neonates with DS may exhibit transient abnormal myelopoiesis (TAM), a preleukemic condition that is unique to infants with DS or mosaic trisomy 21. In most cases, TAM regresses spontaneously, however one-quarter of these children will go on to develop acute leukemia or myelodysplastic syndrome. Acute lymphoblastic leukemia in DS shares genetic features with that occurring in non-DS patients, but with a different distribution of genotypes including a lower level of good-risk subtypes.[132] Myeloid leukemia associated with DS (ML-DS) is a unique form of childhood leukemia that arises before age 4 years in a child with DS and is

estimated at 3-fold to 400-fold that of AML in the general pediatric population.[133] The clinical presentation, pathogenesis, response to treatment, and excellent prognosis distinguish ML-DS from other acute leukemias in children.[134] ML-DS is usually manifest as acute megakaryocytic leukemia, and diagnosis often follows a MDS-like phase with prolonged cytopenias. ML-DS can arise in a child with a history of TAM, but most cases develop in children who were not documented to have TAM. Blasts in TAM and ML-DS patients have overlapping immunophenotypes, including the presence of CD33, CD36, CD48, and the TPO-R, and frequently the megakaryocytic markers CD41, CD42b, and CD61.[135]

Acquired mutations in megakaryocyte transcription factor gene *GATA1* have recently been reported in DS, TAM, and acute megakaryoblastic leukemia.[136] *GATA1* is an essential regulator of numerous hematopoietic lineages, including red blood cells and megakaryocytes.[137] Recent sequencing studies have demonstrated that TAM is driven by the combination of a *GATA1* mutation and trisomy 21 without the need for additional genetic alterations.[138] However, after TAM has resolved, any remaining disease-driving clones can acquire a third hit that leads to development of ML-DS. The most common additional acquired molecular abnormalities are acquired loss-of-function mutations of cohesin complex or epigenetic regulators and gain-of-function mutations of signal transducers or components of the RAS signaling pathway.[135,138,139]

Acute Lymphoblastic Leukemia with Germline Predisposition

Germline mutations in aforementioned *TP53, ETV6,* and Down syndrome predispose to both myeloid neoplasms and B-ALL. Predisposition to B-ALL is also associated with ataxia telangiectasia, Nijmegen breakage syndrome, and constitutional Robertsonian translocation. Two genes that are critical for B-cell development, *PAX5* and *IKZF1,* have been shown to predispose to familial B-ALL when mutated in the germline.

Acute Lymphoblastic Leukemia With Germline *PAX5* Mutation

PAX5 is located on chromosome 9p13 and is required for normal B-cell development.[140] *PAX5* is commonly mutated in sporadic B-ALL via translocations, copy number alterations, or missense variants involving the DNA binding domain, resulting in loss of function and maturation arrest of B-cell progenitors.[141] Several families with increased B-ALL were shown to harbor germline mutations in *PAX5,* primarily involving a conserved residue in the octapeptide domain of the protein p.G183S,[142,143] but other mutations have also been reported, including R38H.[144] Notably, the development of B-ALL in these families was associated with loss of the wild-type copy of *PAX5* via deletion of chromosome 9p, formation of iso or dicentric 9q, or other mechanisms leading to biallelic inactivation of the gene. Not all family members with germline pathogenic *PAX5* mutations develop B-ALL, indicating that penetrance is incomplete. Donor-derived B-ALL has occurred in patients posttransplant who were inadvertently transplanted using healthy related donors who also harbored the germline mutation,[144] underscoring the importance of recognizing patients who may have germline mutations. The bone marrow

morphology and immunophenotype of the B-ALL blasts is similar to that seen in sporadic B-ALL. The prevalence of germline *PAX5* mutations is not currently defined.

Acute Lymphoblastic Leukemia With Germline *IKZF1* Mutation

IKZF1 is located on chromosome 7p12.2 and encodes the transcription factor Ikaros, which plays an important role in lymphoid development.[145] Somatic mutations in *IKZF1,* resulting in loss of function, have been identified in sporadic B-ALL, and in particular BCR-ABL+ B-ALL.[146] Germline mutations in *IKZF1* were later found in families with hypogammaglobulinemia and common variable immunodeficiency with B lymphopenia, and were associated with an increased risk of B-ALL.[147,148] The prevalence is not yet known; however, up to 1% of presumed sporadic B-ALL cases have predicted pathogenic germline variants in *IKZF1*.[148]

Pearls and Pitfalls

Germline predisposition to hematologic malignancy (HM) is more common than previously thought and should be considered:

- Patients with a family history of cancer
- Young age at HM diagnosis (<40 years of age); caveat: *DDX41* mutations associated with HM presentation in older age range overlapping with sporadic HM

- Patients with HM and high variant allele frequency (VAF) mutation in a germline predisposition gene detected on next-generation sequencing (NGS) targeted panel
- Persistence of high VAF mutation in a germline predisposition gene after chemotherapy
- Presence of syndromic or unique features:
    - Telomere biology:
        - Early graying of hair, pulmonary/hepatic fibrosis
        - *DKC1:* dystrophic nails, leukoplakia, hypopigmented skin patches
    - *GATA2* deficiency
        - Immunodeficiency: loss of monocytes, B cells, natural killer (NK) cells, dendritic cells
        - Lymphedema
        - Monosomy 7, trisomy 8 or der (1;7)(q10;p10), *ASXL1* and *STAG2* mutations
    - *RUNX1, ANKRD26, ETV6*
        - Thrombocytopenia since early age/birth
        - Patients may be misdiagnosed with immune thrombocytopenic purpura (ITP)
        - Dysmegakaryopoiesis is common at baseline in the bone marrow and is not sufficient for a diagnosis of myelodysplastic syndrome (MDS) in the absence of other supporting criteria
    - *SAMD9/SAMD9L*
        - Monosomy 7 is common and may lead to lower VAF of mutation as *SAMD9* and *SAMD9L* are located on chromosome 7

- Somatic genetic rescue (SGR) via uniparental disomy in hematopoietic cells is common
- Shwachman-Diamond syndrome
- *TP53* mutations common, biallelic *TP53* mutations associated with HM
  - Syndromic features may not be present
  - Penetrance may be highly variable even within family members harboring the same mutation
  - Patients with de novo germline mutations typically have no family history of disease
  - Gold-standard tissue source for germline testing is cultured skin fibroblasts. Other tissue sources are less optimal. Buccal swabs may contain contamination with hematopoietic cells, making it difficult to distinguish germline mutations from somatic mutations. DNA yield from hair follicles may be low. Nail clippings may be contaminated with monocytes.

DIAGNOSTIC QUALIFIERS IN ACUTE MYELOID LEUKEMIA

INTEGRATED APPROACH TO THE DIAGNOSIS OF ACUTE MYELOID LEUKEMIA

Acute myeloid leukemia (AML) is a heterogeneous group of diseases representing clonal proliferations of immature, nonlymphoid, bone marrow–derived cells termed *blasts* that most often involve the bone marrow and peripheral blood and may present in extramedullary tissues. If untreated, AML follows an aggressive clinical course. AML has traditionally been differentiated from other myeloid neoplasms on the basis of a minimum blast cell count in bone marrow or peripheral blood. Although this remains the case for some disease types, several specific AML types are now defined even in the presence of a relatively low blast cell count.

The French American-British Cooperative Group (FAB) described a number of AML subtypes based originally on morphologic and cytochemical features; other studies, including immunophenotyping and electron microscopy, were added later as defining features of some subtypes.[1-4] The FAB classification defined all AML types as proliferations of 30% or more marrow blasts of either all bone marrow cells or all marrow nonerythroid progenitor cells. Although other classification systems were subsequently proposed to incorporate more comprehensive immunophenotyping studies, cytogenetic studies, and combinations of these two ancillary testing methods,[5-8] the FAB classification remained the primary system used by most pathologists and hematologists for many years. The terminology of the FAB classification continues to be used, but this

system is now considered obsolete owing to its inability to accurately identify many prognostically significant disease types.

The 2001 3rd ed. World Health Organization (WHO) classification of AML incorporated findings not included in the FAB classification, including the significance of therapy-related disease, the significance of recurring cytogenetic abnormalities, and the possible significance of multilineage dysplasia in non–blast cells in AML.[9] These changes partially addressed the concepts of de novo AML versus myelodysplasia-related AML proposed by Head.[10] The 2016 revised 4th ed. WHO classification of AML further expanded and refined the categories first introduced in 2001 and expanded in 2008.[11] In 2022, the International Consensus Classification (ICC) of AML further expanded genetically defined disease groups (**Box 46-1**).[12] Though a proposed WHO 5th ed. classification was published in 2022,[13] many details of that classification remain undefined at the time of the update of this chapter. The ICC approach will be the major focus of this chapter with attempts to correlate the disease categories with what appears to be proposed in the upcoming WHO 5th ed. classification.

SYNONYMS AND RELATED TERMS

None.

EPIDEMIOLOGY

The incidence of AML is approximately 3.5 cases per 100,000 per year. The median age at diagnosis is 67 years, and there is a slight male predominance. The frequency of AML increases with age; approximately 6% of cases occur in children and adults younger than

20 years, and more than 50% of cases occur in patients 65 years of age and older.[14]

ETIOLOGY

The cause of many cases of AML is unknown, particularly those arising in children and young adults. A subset of AML arises from a preexisting myelodysplastic syndrome (MDS) or is a secondary leukemia related to prior therapy for a nonleukemic disorder. AML occurs more commonly in patients with preexisting genetic predisposition syndromes or genetic disorders, including Fanconi's anemia and Down syndrome, and familial cases of AML are now increasingly recognized even in the adult population.[15]

CLINICAL FEATURES

Patients with AML usually are seen with symptoms related to anemia and thrombocytopenia, including fatigue and bleeding, and symptoms related to white blood cell dysfunction, especially infections. They may also have extramedullary tumor proliferations, which appear to be more common in childhood AML.

International Consensus Classification, 2022.

MORPHOLOGY

Most cases of AML have increased bone marrow myeloblasts, which may also be present in the peripheral blood. A variety of blast cell changes may be present, and some are suggestive of specific AML types; however, some general blast cell features occur in most types. For instance, blasts have immature nuclear chromatin, characterized by a lack of chromatin clumping and the presence of nucleoli. Myeloblast nuclei may be round or have nuclear invaginations. Variable numbers of cytoplasmic granules may be present in myeloblasts, but such granules identified on Wright-stained smears are not lineage specific. The presence of coalesced granules that form rod-shaped cytoplasmic bodies (Auer rods) is considered specific for myeloid lineage. Monoblasts may range from cells with round nuclei and moderate basophilic cytoplasm, with or without vacuoles, to more intermediate cells (promonocytes) with similar immature nuclear chromatin but more folded nuclear features, similar to mature monocytes. The morphologic features of non–blast cell elements of the blood and marrow are also markers of potential genetic abnormalities and are discussed in more detail under the specific disease types.

CYTOCHEMISTRY

Cytochemical studies were used extensively in the past to assign lineage to acute leukemias and to subclassify AML in the FAB classification. These studies have now been largely supplanted by immunophenotyping and are no longer necessary for the diagnosis of most cases of AML. However, a limited cytochemical panel of myeloperoxidase (or Sudan black B for older smears) and non-specific esterase can be helpful in selected cases. A very strong

myeloperoxidase cytochemical reaction may be useful in distinguishing acute promyelocytic leukemia (APL) from monocytic leukemia, and cytochemical studies can be helpful in subclassifying cases of AML, not otherwise specified (AML, NOS).

IMMUNOPHENOTYPE

Immunophenotyping studies are now performed in all cases of acute leukemia to distinguish myeloid from lymphoblastic lineage and to identify acute leukemias of ambiguous lineage. Multiparameter flow cytometric methods with CD45/side scatter gating are preferred because of the large number of antigens that can be studied quickly with this method.[16,17] Immunophenotyping studies are often helpful in subclassifying the various types of AML.[18] The specific features of each are described later and in Chapter 4. In addition, flow cytometric immunophenotyping studies at diagnosis can identify aberrant patterns of antigen expression on the leukemic cells, which can be useful in searching for minimal residual disease in post-therapy samples.

GENETICS

The role of genetic changes in AML has been the subject of intense study and has been facilitated by the diagnostic use of next-generation sequencing (NGS) techniques. Karyotype analysis is essential in all cases of AML, and these findings play a major role in the proper classification of these leukemias.[19,20]

Initially, the focus on gene mutations in AML was directed toward cases with a normal karyotype,[21,22] but subsequent studies included all AML types and both genetic and epigenetic changes.[23-25]

Mutations were initially divided into two types. So-called “type I” (or “class I”) mutations impart a proliferation or survival advantage without affecting differentiation.[26] These are often later events in the development of leukemia and are generally viewed as prognostic markers. Receptor tyrosine kinase mutations are common type I mutations in AML. Mutations in *FLT3* and *KIT* are the most common clinically relevant type I abnormalities used in AML stratification. *FLT3* is expressed on hematopoietic progenitors. Activation through ligand binding, or constitutive activation from *FLT3* mutations, leads to cell proliferation and survival. So-called “type II” (or “class II”) mutations impair hematopoietic cell differentiation and subsequent programmed cell death (apoptosis).[26] These are thought to be primary genetic events in the development of AML and are viewed as disease-defining abnormalities rather than simply prognostic factors. Many of the gene fusions involved in the AML with recurring cytogenetic abnormalities described previously fall into this group. In addition, mutations of CCAAT/enhancer binding protein-α *(CEBPA)*, *RUNX1,* and probably nucleophosmin *(NPM1)* are type II mutations. As such, mutations in *NPM1* and *CEBPA* tend to occur in cases of AML with normal cytogenetics and define unique clinicobiological entities with favorable prognoses in the absence of *FLT3* abnormalities. Class II translocations and mutations defined specific disease categories in the WHO classification. It is now understood, however, that there are more than two classes of mutations in AML,[23] that not all “disease-defining” mutations are the initial genetic event,[27,28] and that most AML cases have more than a single mutation (so-called “cooperating

mutations"),[24,25] and some groups of genes may define prognostic AML types when one or more genes in the group are mutated.[29-31]

FLT3, KIT, and many of the other more recently described mutations do not define exclusive categories of AML because they are present in many of the previously described diagnostic categories. *FLT3* abnormalities include internal tandem duplications (ITDs) and tyrosine kinase domain point/juxtamembrane domain (TKD) mutations.[32] *FLT3*-ITD mutations are associated with shorter remission duration and shorter overall survival (OS) for most AML types. The ratio of mutant *FLT3* to wild-type allele can identify patients with poor outcomes. *KIT* mutations appear most commonly and have the most clinical relevance in core binding factor leukemias,[33] especially adults with AML with t(8;21)(q22;q22.1). In contrast, *FLT3*-ITDs are rare in core binding factor leukemias and in AML with *KMT2A* translocations. Therefore the various cooperating gene mutations associated with the different AML subtypes are discussed in those sections throughout the chapter.

Although not a discrete AML type in most classifications, detection of *FLT3* mutations in AML are important for prognostic reasons and to identify patients that might benefit from targeted therapies directed against the mutation.[34]

An increasing number of targeted therapies have emerged related to gene mutations, and mutation panels are now routinely performed at the time of diagnosis for most AML cases. Some gene mutations associated with AML are germline mutations, and their recognition is important for screening of family members (see Chapter 45).

Mutation analysis for a growing number of genes is also needed to determine the prognosis, and in some cases the diagnosis, of AML

types. Evaluation for mutations of *FLT3,* particularly for ITDs, is indicated in all cases in current guidelines. In addition, most, if not all, AMLs should now be tested with a large gene mutation panel that includes *ASXL1, BCOR, CEBPA, EZH2, NPM1, RUNX1, SF3B1, SRSF2, STAG2, TP53, U2AF1,* and *ZRSR2*.[12,29,30] More rapid evaluation of *FLT3, IDH1,* and *IDH2* is becoming necessary because of targeted therapies that are now used in up-front treatment regimens.[35] Evaluation for mutations of *KIT* are of value in AML with t(8;21)(q22;q22.1) (*RUNX1*::*RUNX1T1*) and AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) (*CBFB*::*MYH11*).[33] Other gene mutations are of emerging prognostic significance in AML and may be also included in NGS mutation panels.[23]

In addition to mutations, overexpression of some genes has prognostic significance. In particular, *MECOM* (previously known as *EVI1*) is inappropriately expressed in a variety of AMLs, including AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2), and high expression of *MECOM* is a poor prognostic indicator independent of 3q26.2 translocations.[36] Overexpression of the *MECOM (EVI1)* gene has also been described in multiple variant translocations of 11q23.3 and is associated with a very poor prognosis.[37] Some data suggest that *MECOM*-positive AML with *KMT2A* translocations is biologically different from *MECOM*-negative cases,[38,39] but in the ICC the presence of a *KMT2A* translocation trumps a *MECOM* abnormality in the diagnostic hierarchy.

PROGNOSIS

The overall 5-year survival rate for AML is between 20% and 25%, but it varies by disease type.[14]

ACUTE MYELOID LEUKEMIA DISEASE TYPES

Although many AML types have distinctive morphologic, clinical, and prognostic features in addition to the specific cytogenetic and molecular genetic findings,[18,20] the ICC approach to AML is primarily based on genetics with nongenetically defined disorders placed in the ever-shrinking category of AML, NOS.[12] In addition to a more genetic approach, the ICC also makes major changes related to blast cell counts required for an AML diagnosis. Many of the genetically defined abnormalities in de novo AML types define biologically distinct entities in which the biology does not change based on blast cell count. The best characterized of these is APL with t(15;17)(q24.1;q21.2)/*PML*::*RARA* and the core binding factor leukemias (AML with t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1* and AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*) and prior classifications have allowed for a diagnosis of AML in such cases without regard to blast cell count.[40] The ICC expands the list of de novo type genetic groups, but there is less data on some of these types to be confident that such a finding in the absence of an increase in blasts warrants a diagnosis of AML. Additionally, mutations in *NPM1* may be secondary, such as in the setting of chronic myelomonocytic leukemia (CMML),[41] and such a finding in that context should not automatically trigger a diagnosis of AML. For consistency among disease groups, the ICC requires at least 10% peripheral blood or bone marrow blasts for a diagnosis of AML, understanding that rare cases, especially with features of APL or core binding factor leukemias, may be exceptions to this cutoff. One exception to this approach, however, is AML with (9;22)

(q34.1;q11.2)/*BCR*::*ABL1* for which the 20% blast requirement is retained because of difficulty in distinguishing accelerated phase of CML from AML in cases with less than 20% blast cells. For cases of AML with mutated *TP53,* AML with myelodysplasia-related gene mutations, AML with myelodysplasia-related cytogenetic abnormalities, and AML, NOS, the 20% blast requirement is retained, but a new category of MDS/AML is introduced in which peripheral blood or marrow blasts are 10% to 19%. Such cases should be treated based on their clinical behavior, with some being slowly progressive, similar to MDS, and others progressing quickly, similar to AML.[42]

Acute Promyelocytic Leukemia With t(15;17)(q24.1;q21.2)/*PML*::*RARA*

APL usually has an abrupt onset, and it constitutes 5% to 8% of AML cases. It is most common in young adults, rarely occurring before 10 years of age and diminishing in incidence after age 60 years. Organomegaly is uncommon. Prompt diagnosis is essential because of the high frequency of life-threatening disseminated intravascular coagulation. The t(15;17)(q24.1;q21.2) results in fusion of the promyelocytic gene *(PML)* on chromosome 15 with the retinoic acid receptor *(RARA)* gene on chromosome 17. The blasts are highly sensitive to anthracycline-based chemotherapy and differentiate in response to all-*trans*retinoic acid (ATRA) and arsenic trioxide treatment.[43,44]

Two morphologic variants are common. Hypergranular or typical APL accounts for 60% to 70% of cases and usually presents with a low white blood cell count (**Box 46-2**). Hypogranular or

microgranular APL typically presents with leukocytosis, with numerous circulating abnormal promyelocytes.[45,46] Both forms have abnormal reniform or bilobed nuclei, and recognition of these characteristic nuclear features is an important element of the diagnosis. In hypergranular APL, the abnormal promyelocytes have numerous red to purple cytoplasmic granules (**Fig. 46-1A**). The granules are often larger and more darkly stained than normal neutrophil granules, and they may be so numerous that they obscure the nuclear borders. In some cases, a high percentage of leukemic cells have deeply basophilic, granular cytoplasm. Cells containing multiple Auer rods are reportedly found in up to 90% of cases of the hypergranular form. The Auer rods may be numerous and intertwined. Large globular inclusions of Auer rod–like material are found in the cytoplasm of occasional cells. Typical myeloblasts are a minor component in most cases, rarely reaching 20%. The abnormal promyelocytes are considered comparable to blasts for the purpose of diagnosing APL. In the microgranular variant of APL, the leukemic cells have sparse or fine granulation and markedly irregular nuclei (**Fig. 46-1B**). The bilobed or butterfly-shaped nuclei should raise suspicion of the microgranular variant. Cells containing multiple Auer rods are less abundant than in typical hypergranular APL. Myeloperoxidase and Sudan black B reactions are similarly strong in both variants.

Box 46-2 Key Features of Acute Promyelocytic Leukemia With t(15;17)(q24.1;q21.2)/*PML*::*RARA*

- Hypergranular type exhibits abundant cytoplasmic granules and bundles of Auer rods
- Characteristic myeloid-lineage immunophenotype, with weak or absent HLA-DR and absent CD34
- Hypogranular type exhibits indistinct granules and folded nuclei and is often CD34 positive
- Common association with disseminated intravascular coagulation
- Favorable prognosis in cases that are *FLT3* negative and treated with combination all-*trans*retinoic acid and arsenic trioxide

The immunophenotype of hypergranular APL displays increased side scatter, lack of expression of HLA-DR and CD34, bright CD33, bright cytoplasmic myeloperoxidase, and variable expression of CD13.[47,48] The microgranular variant shows similar CD13, CD33, and myeloperoxidase expression but may show dim HLA-DR and commonly demonstrates dim CD34. The CD34-negative, HLA-DR-negative immunophenotype is not specific to APL[49]; it is also observed in some cases of cytogenetically normal AML without differentiation. Expression of CD15 is uncommon. CD117 is expressed in both morphologic variants. Many cases exhibit CD64 expression, and caution is warranted to avoid misdiagnosing microgranular APL as AML with monocytic differentiation. Aberrant expression of CD2 is more commonly observed in microgranular APL[50] and has been associated with *FLT3*-ITD mutations.[51] CD56 expression is described in 15% to 20% of patients with APL and has

been associated with shorter complete remissions and poorer OS in some studies.[52,53]

Three breakpoint regions are described on the *PML* gene at band q24.1 of chromosome 15.[54] Two lead to long transcripts, and the third leads to the short transcript. The short transcript is more common in the microgranular variant. Cytogenetics, fluorescence in situ hybridization (FISH), or reverse transcriptase polymerase chain reaction (RT-PCR) is necessary for genetic confirmation of the *PML*::*RARA* fusion. FISH, RT-PCR, and immunofluorescence for the microspeckled nuclear distribution of PML protein may facilitate a rapid diagnosis.[55] RT-PCR is the only technique that can identify the *PML*::*RARA* isoform useful for the monitoring of minimal residual disease.[56] The PML::RARA fusion protein mediates a block in myeloid differentiation, which can be overcome with ATRA or arsenic trioxide therapy. ATRA targets the RARA component of the fusion protein, whereas arsenic trioxide targets PML, causing maturation and apoptosis. In most cases, remission can be achieved with ATRA alone, but relapse invariably occurs. Therefore standard induction chemotherapy with high-dose anthracyclines was generally given with or after ATRA, though more recent combinations of ATRA and arsenic trioxide do not require the addition of standard chemotherapy in most patients.[57] In adult patients who achieve complete remission, the prognosis is better than for any other category of AML. Rapid diagnosis and initiation of therapy are critical in APL. Because of the high risk of early death and the high potential for cure, initiation of therapy should not await genetic confirmation when clinical, morphologic, flow cytometric, and rapid molecular pathology results all suggest a diagnosis of APL.

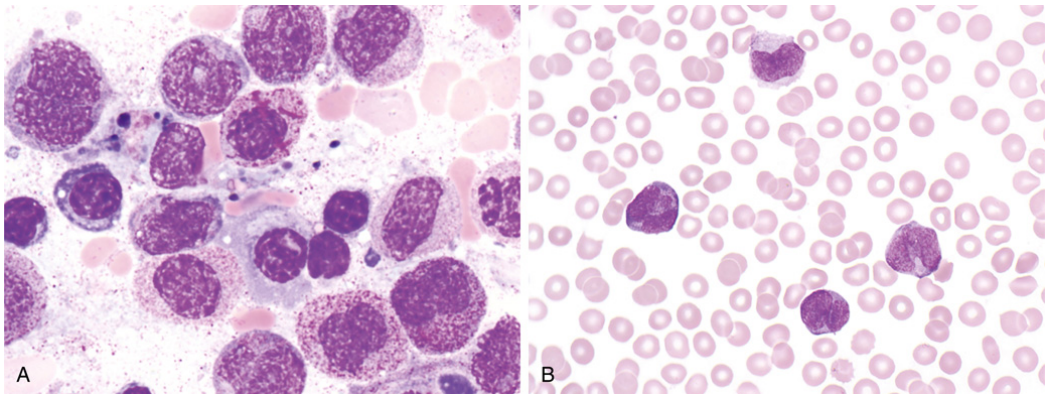

FIGURE 46-1 Acute promyelocytic leukemia with t(15;17)(q24.1;q21.2)/*PML*::*RARA*.**A,** Bone marrow aspirate shows increased promyelocytes and blasts with folded nuclei and numerous cytoplasmic granules, characteristic of the hypergranular type of acute promyelocytic leukemia. Note one blast in the upper center of the panel exhibiting Auer rods. **B,** Peripheral blood from another case shows blasts with bilobed nuclei and less obvious cytoplasmic granules, characteristic of the microgranular variant of acute promyelocytic leukemia.

FLT3 mutations are common in APL[58-60] and occur in approximately 40% of patients, with the majority being ITD mutations. *FLT3*-ITD in APL is strongly associated with the microgranular subtype, high white blood cell counts in peripheral blood, and breakpoint region 3 (short form) in *PML*. In one retrospective study, patients with mutant *FLT3* had a higher rate of death during the induction of chemotherapy but no significant difference in relapse rate or 5-year OS. The significance of the

various historic prognostic factors in APL is unclear with current therapies that combine ATRA with arsenic trioxide.

Atypical promyelocytes may persist in the marrow for several weeks after induction chemotherapy, as may the detection of *PML*::*RARA* by karyotyping, FISH, or RT-PCR. These findings do not necessarily indicate resistant disease. The postinduction detection of *PML*::*RARA* by RT-PCR does not affect subsequent clinical outcome. However, detection of *PML*::*RARA* after complete remission is obtained strongly predicts the risk of relapse.

The differential diagnosis of the hypergranular variant of APL includes agranulocytosis with arrested maturation at the promyelocyte stage. With careful assessment, this distinction can usually be made quickly. In cases of agranulocytosis, the platelet count and hemoglobin level are generally normal, the marrow is not hypercellular, the nuclear features of neoplastic promyelocytes are not present, and Auer rods are not observed. The immunophenotypic differential diagnosis includes cases of HLA-DR–negative, CD34-negative AML, usually AML without differentiation or AML with mutated *NPM1*. These cases can be distinguished by the abnormal "butterfly" nuclei and cytoplasmic granulation of APL. Cases of HLA-DR–negative, CD34-negative AML with mutated *NPM1* often shows the "fish-mouth" deformity or cuplike nuclear inclusions (**Fig. 46-2**). The microgranular variant of APL may mimic AML types with monocytic differentiation, also displaying folded nuclei. Strong myeloperoxidase reactivity by cytochemistry or flow cytometry can resolve this dilemma. In difficult cases, rapid FISH or RT-PCR assessment for the *PML*::*RARA* fusion can be requested, but in most

cases, treatment should not be delayed for molecular genetic confirmation.

Acute Promyelocytic Leukemia With Other *RARA* Rearrangements

Uncommonly, a case with many of the morphologic, immunophenotypic, and clinical features of promyelocytic leukemia has a variant cytogenetic translocation that involves the *RARA* gene on chromosome 17 but not the *PML* gene on chromosome 15.[61-63] **Box 46-3** lists the *RARA* fusions included in the ICC. The t(11;17)(q23.1;q21.2) (*ZBTB16*::*RARA;* formerly known as *PLZF*::*RARA*) is the best-described translocation. The morphology differs from that of hypergranular or microgranular APL in that the majority of blast cell nuclei are round to oval (**Fig. 46-3**), Auer rods are usually absent, and pelgeroid neutrophils may be seen. Patients with variant *RARA* translocations often experience disseminated intravascular coagulation. These cases are important to recognize because although they have many of the features of typical APL, some variants, including those with *ZBTB16*::*RARA,* do not respond to ATRA therapy.

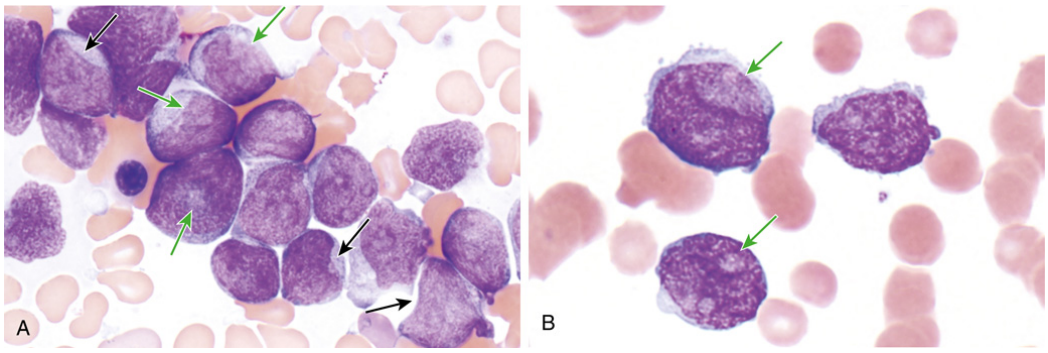

FIGURE 46-2 Acute myeloid leukemia with mutated *NPM1* displaying cuplike nuclear inclusions.**A** and **B,** Nuclear indentations from the side are most obvious *(black arrows);* from other angles, they may appear as large, pale nucleoli *(green arrows)*. These features are reportedly associated with *NPM1* mutations.

Acute Myeloid Leukemia With t(8;21)(q22;q22.1)/*RUNX1::RUNX1T1*

AML with t(8;21)(q22;q22.1) has distinctive morphologic and immunophenotypic findings that correlate well with a specific cytogenetic abnormality (**Box 46-4**).[64-66] This type of leukemia is common in both children and adults, accounting for approximately 8% of AML. Although blasts are common in both blood and bone marrow, the morphologic features are more distinctive in the bone marrow. The blasts in the bone marrow have perinuclear cytoplasmic hoflike clearing, occasional Auer rods, and occasional large, salmon-colored granules (**Fig. 46-4**). Abundant granules may suggest a promyelocyte proliferation, but these granular cells are the neoplastic cells and should be considered blasts. The maturing neutrophils are usually dysplastic, with nuclear abnormalities; background eosinophilia is often present, without morphologic abnormalities of the eosinophils. The bone marrow biopsy is usually hypercellular, with sheets of immature cells. The abundance of granules and cytoplasm in the cells may give the appearance of a left shift on biopsy sections rather than a definite blast cell increase, and the distinctive blast cell features are best identified on aspirate smears. The blasts are large, with a background of myeloid maturation; however, the features are more distinctive than just the myeloid maturation of the heterogeneous group of FAB M2 AML. Cases may also present as extramedullary disease (myeloid sarcoma), especially in children.

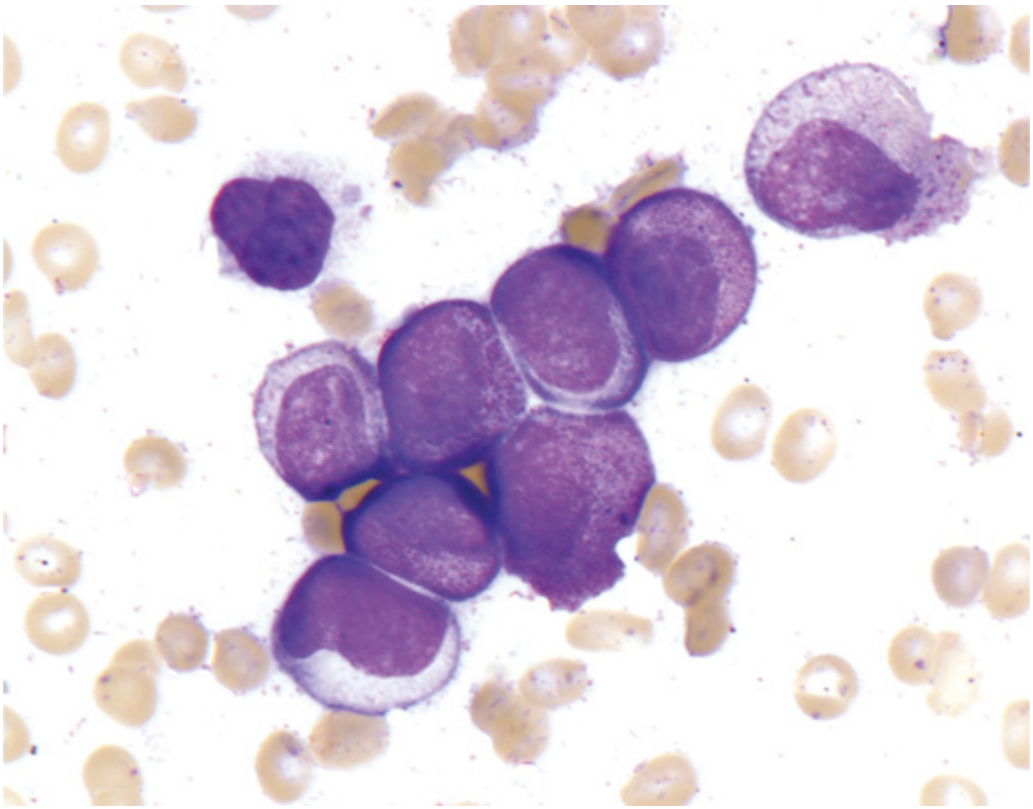

FIGURE 46-3 Acute promyelocytic leukemia with t(11;17)(q23.2;q21.2)/*ZBTB16*::*RARA*.This rare type of acute promyelocytic leukemia is associated with abundant cytoplasmic granules, similar to the more common acute promyelocytic leukemia with *PML*::*RARA*. However, it has more round to oval blast cell nuclei, rather than the typical bilobed nuclei of the disease with *PML*::*RARA*.

Box 46-4 Key Features of Acute Myeloid Leukemia With t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1*

- Blasts with perinuclear hofs, abundant granules, and large pink or salmon-colored granules
- Myeloid-lineage blasts expressing CD34 and CD19
- Favorable prognosis when presenting with white blood cell count $<20 \times 10^9$/L and absence of *KIT* mutations

Immunophenotypically, cases express CD34, with usually strong expression of CD13 and HLA-DR and more variable expression of CD33. Myeloperoxidase is easily detected by either cytochemistry or flow cytometry. There is aberrant expression of the B-lymphocyte–associated surface antigen CD19 (weak) in the majority of cases, and many cases also express CD56.[64-66] Some studies suggest that CD56 expression is associated with increased relapse in this disease group.[67] PAX5 is frequently expressed when cases are studied by immunohistochemistry, and CD79a may be expressed in some cases.[68]

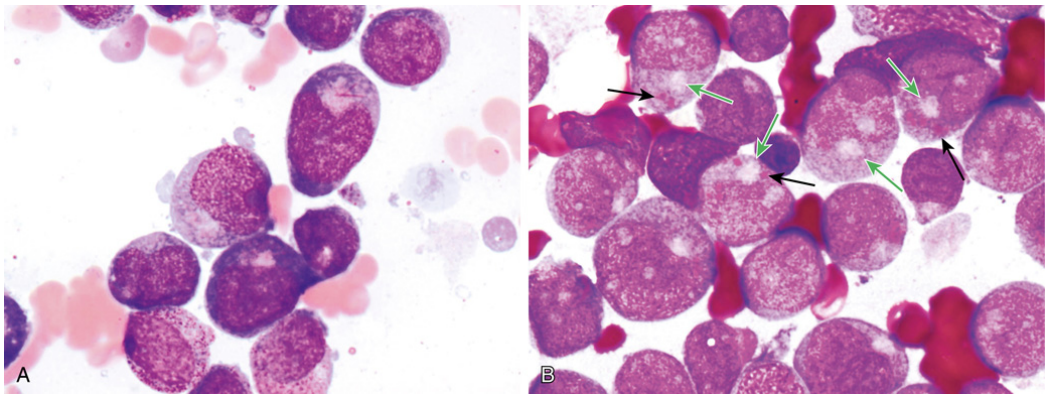

FIGURE 46-4 Acute myeloid leukemia (AML) with t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1*.**A,** Blasts show a variable number of granules, suggesting cell maturation. One blast contains thin Auer rods. **B,** Perinuclear hofs *(green arrows)* and large pink granules *(black arrows)* are characteristic features of this type of AML.

The t(8;21)(q22;q22.1) is usually easily detected by karyotype analysis and results in the fusion of *RUNX1* (also known as core binding factor-α and *AML1*) on chromosome 21, band q22.1, and *RUNX1T1* (also known as *ETO*) on chromosome 8, band q22. The translocation disrupts function of the core binding factor (which has both alpha and beta subunits) that is normally involved in regulating hematopoiesis.[69] AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) (*CBFB*::*MYH11*) disrupts the beta subunit of the core binding factor, and these two AML types are commonly referred to as the *core binding factor leukemias*. Core binding factor leukemias are associated with a favorable prognosis in children and adults,[70] especially when treated with repetitive cycles of high-dose cytarabine (HiDAC) after remission. Cases of t(8;21) AML with a white blood cell count greater than 20×10^9/L at presentation appear to behave

more like intermediate-risk disease, and patients may benefit from allogeneic hematopoietic cell transplantation during the first remission. Mutations of *KIT* in core binding factor AML are common (20%–25%).[33] In adults, *KIT* mutations in exons 8 and 17 appear to be associated with a worse prognosis. It is unclear whether they have a similar prognostic effect in children, or whether t(8;21) AML with *KIT* mutation benefits from allogeneic hematopoietic cell transplantation during the first remission. Mutations in *FLT3* are uncommon in core binding factor leukemia. However, mutations of *KRAS, NRAS, ASXL1,* and *ASXL2* do occur in subsets of patients with AML with t(8;21)(q22;q22.1).[71,72] Additional cytogenetic abnormalities are present in more than 70% of t(8;21) AML, most commonly loss of a sex chromosome or partial deletion of the long arm of chromosome 9 (del[9q]). In general, the presence of additional cytogenetic abnormalities in this disease group does not have prognostic significance. After therapy, RT-PCR may detect *RUNX1*::*RUNX1T1* transcripts in the absence of clinical disease. The messenger RNA can be detected in some stem cells, mature monocytes, and hematopoietic progenitors during remission; detection of low levels of this fusion transcript is of unclear significance. Quantitative RT-PCR for *RUNX1*::*RUNX1T1* transcripts is more useful for monitoring of minimal residual disease.[73]

The differential diagnosis of AML with t(8;21)(q22;q22.1) includes APL, mixed phenotype acute leukemia, MDS, and regenerative changes that include the effects of growth factors. APL exhibits more folded blast cell nuclei and finer cytoplasmic granules than AML with t(8;21)(q22;q22.1). Immunophenotypic studies can also distinguish between these AML types, with APL usually lacking CD34, HLA-DR,

and CD19, markers that are positive in the majority of cases of AML with t(8;21)(q22;q22.1). Despite the common expression of B-cell–associated antigens in AML with t(8;21)(q22;q22.1), these cases should not be diagnosed as mixed phenotype acute leukemias. The distinctive morphologic features of AML with t(8;21)(q22;q22.1), coupled with the characteristic immunophenotype of myeloid antigen expression with CD34 and CD19, warrant investigation for t(8;21) before a diagnosis of mixed phenotype leukemia is considered. On occasion, AML with t(8;21)(q22;q22.1) presents with a blast count less than 20% at diagnosis. Although these cases meet the criteria for MDS with excess blasts or MDS/AML, when treated appropriately, they behave similarly to other cases of AML with t(8;21)(q22;q22.1) and should be diagnosed as such rather than as myelodysplasia. If the abnormal cells with abundant granules of this AML type are counted as blasts, the vast majority will meet the 10% blast requirement of the current ICC. Patients recovering from toxic events or receiving granulocyte or granulocyte-monocyte colony-stimulating factor may show a marrow proliferation of promyelocytes with perinuclear hofs which may partially resemble blasts seen in AML with t(8;21)(q22;q22.1). These reactive proliferations do not contain Auer rods and usually do not exhibit the distinct, large, salmon or pink granules of AML. Investigation of the blood often shows toxic granulation of neutrophils associated with reactive promyelocyte proliferations, which is not usually seen with AML. Finally, reactive promyelocytes are usually CD34 negative and always CD19 negative, features that can help in the differential diagnosis. This differential diagnosis is particularly difficult in post-therapy patients with a history of AML with t(8;21)(q22;q22.1) who

are receiving growth factors. In such cases, correlation with cytogenetic studies is helpful. In addition, a repeat bone marrow biopsy 2 weeks after cessation of growth factor should clarify whether the cell proliferation in question represents regenerative promyelocytes (which mature over time) or leukemic cells (which persist).

Acute Myeloid Leukemia With inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*

AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) accounts for less than 10% of adult AML and approximately 6% of childhood AML. The inv(16)(p13.1q22) is a pericentric inversion of chromosome 16. The genes at the breakpoint junction are the beta subunit of the core binding factor *(CBFB)* at 16q22 and a gene-encoding smooth muscle myosin heavy chain *(MYH11)* at 16p13.1.[74] AML with inv(16) usually has a characteristic morphology of acute myelomonocytic leukemia with abnormal eosinophils (AML M4Eo in the FAB classification) in the bone marrow (**Box 46-5**).[75] Typical myeloblasts, monoblasts, promonocytes, and mature monocytes are seen in the peripheral blood and marrow, with increased and dysplastic or abnormal eosinophils in the marrow (**Fig. 46-5**). The abnormal eosinophils have abundant and large, often irregularly shaped, basophilic-staining granules. These cells, however, may be admixed with normal-appearing eosinophils and are often absent in the peripheral blood. Flow cytometric immunophenotyping typically reveals multiple populations, including an immature blast population expressing CD34 or CD117, or both, as well as groups of cells exhibiting granulocytic (CD13, CD33, CD15, myeloperoxidase) or

monocytic (CD4, CD11b, CD11c, CD14, CD64, CD36, lysozyme) differentiation. Aberrant co-expression of CD2 in the blast population occurs in a subset of cases,[76,77] but it is not specific for this type of AML.

The incidence of extramedullary disease in AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) is reportedly as high as 50%, higher than for most types of AML. Similarly, lymphadenopathy and hepatomegaly are particularly common. Myeloid sarcoma may precede or present concurrently with bone marrow involvement. Some investigators have reported a high incidence of central nervous system relapse with intracerebral myeloid proliferations. Like AML with t(8;21), this core binding factor leukemia has a generally favorable prognosis.[78,79] *KIT* mutations are present in approximately 30% of cases, and exon 8 mutations in particular reportedly have a negative effect on prognosis in adults.[33] A co-existing trisomy 22 is associated with an improved prognosis, whereas trisomy 8 and tyrosine kinase domain mutations of *FLT3* are associated with a worse prognosis.[71,80] Levels of the *CBFB*::*MYH11* transcript detected by RT-PCR decrease slowly after therapy, and patients may continue to test positive during early complete remission.[81] Molecular remissions are possible and correlate well with long-term remission.

The differential diagnosis of AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22) includes myelomonocytic types of AML, NOS; MDS/myeloproliferative neoplasm (MPN); and reactive monocytic proliferations. In a small subset of cases of AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22), abnormal eosinophils are very scarce or even absent, and the diagnosis can be made only when the

karyotype studies are complete. To complicate matters, inv(16)(p13.1q22) is often subtle and may be missed on routine karyotyping. Therefore the laboratory performing the karyotype analysis should be informed if abnormal eosinophils are identified and inv(16)(p13.1q22) is suspected, and other studies, such as FISH, should be performed before a sample with abnormal eosinophils is considered negative for inv(16)(p13.1q22) or t(16;16)(p13.1;q22). The presence of an increase in normal-appearing eosinophils may occur with other AML types and is not specific for a diagnosis of AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22). Some patients with this type of AML present with numerous eosinophils, at least some of which are abnormal, as well as numerous monocytes, so that the marrow blast cell count falls below 20%. Such cases should not be considered MDS or CMML but rather AML if inv(16)(p13.1q22) or t(16;16)(p13.1;q22) is detectable. Finally, reactive monocytosis should not demonstrate an increase in blasts and promonocytes or abnormal eosinophils, which, along with detection of the karyotype abnormality, are the most helpful indicators of AML in this differential diagnosis.

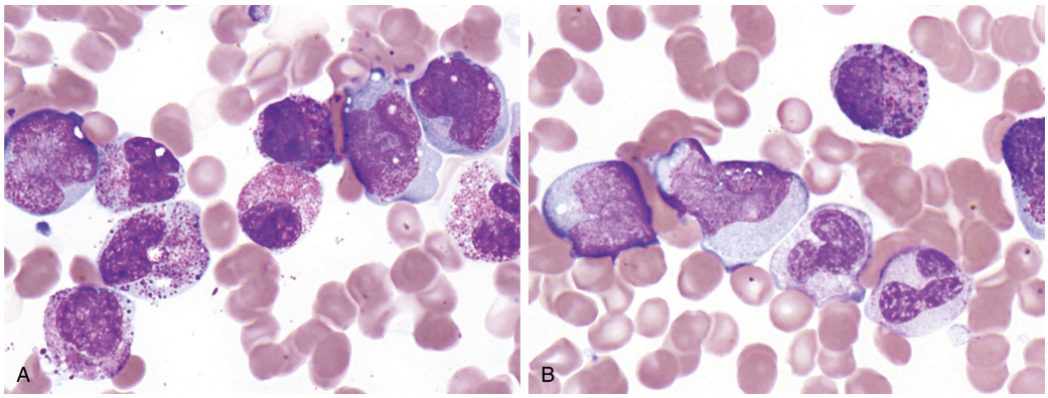

FIGURE 46-5 Acute myeloid leukemia with inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*.Both cases show blasts with monocytoid nuclear features and abundant cytoplasm. One of the cases **(A)** exhibits numerous eosinophil precursors, some of which have the characteristic large basophilic granules. The other one **(B)** shows only a single abnormal eosinophil.

Box 46-5 Key Features of Acute Myeloid Leukemia With inv(16)(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11*

- Blasts have myelomonocytic features
- Abnormal eosinophils contain large, basophilic granules
- Favorable prognosis in the absence of *KIT* mutations

Acute Myeloid Leukemia With t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*

Translocations involving the *KMT2A* gene (previously known as *MLL*) on chromosome 11q23.3 are found in approximately 6% of cases of AML and are associated with more than 100 different partner genes.[82-86] In addition to de novo AML, *KMT2A* rearrangements are common in therapy-related myeloid proliferations, acute lymphoblastic leukemia (ALL), and acute leukemias of ambiguous lineage. AML with t(9;11)(p21.3;q23.3) typically occurs in children and has an intermediate prognosis (**Box 46-6**).[87] These patients may present with disseminated intravascular coagulation or extramedullary disease involving the gingiva and skin. The blasts typically have monocytic or myelomonocytic morphology, although they occasionally lack differentiation (**Fig. 46-6**). Cases composed morphologically of mostly monoblasts and promonocytes are typically myeloperoxidase negative by cytochemistry. In children, AML with t(9;11)(p21.3;q23.3) expresses CD33, CD4, CD65, and HLA-DR, with minimal or no CD13, CD14, and CD34 expression.[88] In adults, AML with 11q23.3 translocations often shows monocytic morphologic differentiation and may express multiple monocytic antigens, including CD14, CD64, CD11b, CD11c, and CD4. CD34 is often negative, with variable CD117 and CD56 reactivity.[89]

Box 46-6 Key Features of Acute Myeloid Leukemia With t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*

- Typically occurs in childhood
- Monocytic morphology of blast cells most common
- Intermediate prognosis

Approximately 20% of AML cases with t(9;11)(p21.3;q23.3) have activating loop domain point mutations in *FLT3,* but these are of uncertain prognostic significance. Pediatric AML with t(9;11)(p21.3;q23.3) has an intermediate prognosis, whereas leukemias with an 11q23.3 translocation involving a different partner chromosome generally have a poorer prognosis.

The differential diagnosis of AML with t(9;11)(p21.3;q23.3) includes various categories of AML, NOS and mixed-phenotype acute leukemia. The morphologic and immunophenotypic features cannot resolve the differential diagnosis with AML, NOS; proper classification depends on the cytogenetic findings. Though a history of prior cytotoxic therapy took precedence over this AML category in prior classifications, such therapy-related cases are now diagnosed based on their genetic findings with the prior therapy noted in the diagnosis as a qualifier. Cases that meet immunophenotypic criteria for mixed phenotype acute leukemia with *KMT2A* rearranged may be designated as such, but the presence of t(9;11)(p21.3;q23.3) should be clearly designated because this may be a more important prognostic finding than the mixed phenotype.

Acute Myeloid Leukemia With Other *KMT2A* Rearrangements

AML with balanced translocations of 11q23.3 other than t(9;11)(p21.3;q23.3) are diagnosed separately from AML with t(9;11)

(p21.3;q23.3)/*MLLT3*::*KMT2A*. **Box 46-7** lists the other *KMT2A* translocations in AML included in the ICC, although many more are now reported in acute leukemia.[86] Gene mutations in *KIT* or *FLT3*-ITD are uncommon in AML with *KMT2A* translocations.

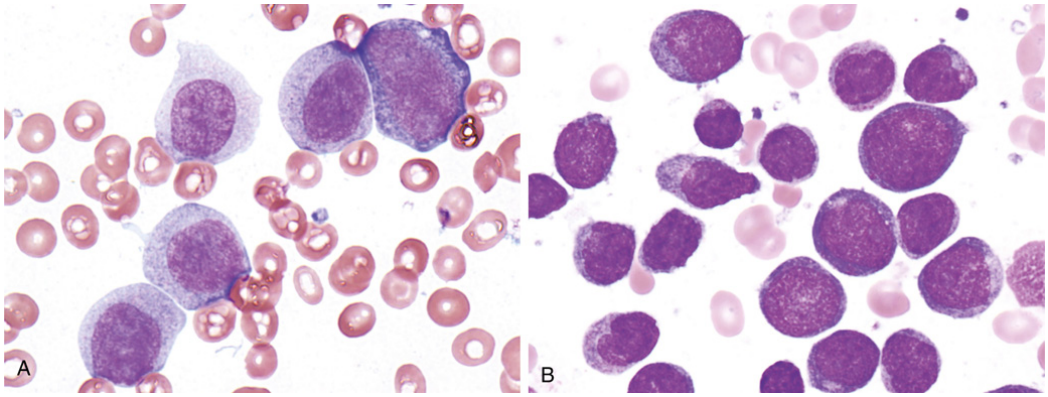

FIGURE 46-6 Acute myeloid leukemia with t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*.The morphologic appearance is variable. **A,** This case shows abundant basophilic cytoplasm, suggestive of monocytic differentiation. **B,** This other case shows blasts with a more myeloblastic appearance, including some cells with granules. Although myelomonocytic or monocytic features are most common, there are no specific morphologic features of this translocation.

Acute Myeloid Leukemia With t(6;9)(p22.3;q34.1)/*DEK*::*NUP214*

AML with t(6;9)(p22.3;q34.1) is a rare subtype accounting for approximately 1% of cases in both children and adults.[90-93] The

median age in adults with this subtype of AML is 35 years. The translocation is reported in de novo AML, AML arising from MDS, and, less commonly, postcytotoxic therapy. Most cases would have been classified as AML with multilineage dysplasia in the 2001 3rd ed. WHO classification and meet the criteria for a variety of morphologic AML types, other than APL (**Box 46-8**). Adults with AML with t(6;9)(p22.3;q34.1) tend to have low white blood cell counts compared with other types of AML. Children may have more profound anemia. The blasts of AML with t(6;9)(p22.3;q34.1) may show occasional Auer rods and may exhibit monocytic features. Anisopoikilocytosis, circulating nucleated red blood cells, hypogranular neutrophils, and hypogranular platelets may be seen on the peripheral blood smear. Residual myeloid maturation is often present in the marrow, with dysplastic-appearing mature forms. Erythroid hyperplasia with dyserythropoiesis is also common, including ring sideroblasts in some cases. Small hypolobated megakaryocytes may be seen (**Fig. 46-7**). Basophilia (>2% marrow or blood basophils) is present in roughly half of reported cases, a feature unique to this type of AML. By flow cytometry, blasts typically express CD45, CD13, CD33, HLA-DR, and intracytoplasmic myeloperoxidase, with variable expression of CD34, CD15, and CD11c. Terminal deoxynucleotidyl transferase (TdT) may be positive in some cases by flow cytometry or immunohistochemistry.[93] *FLT3*-ITD mutations are common in this type of AML,[91,93,94] with a reported frequency of 70% to 80%. Although the majority of patients with t(6;9) AML may achieve complete remission, survival rates are very poor with conventional chemotherapy. As in other high-risk categories of AML, patients may benefit from allogeneic

hematopoietic cell transplantation. It appears that the poor prognosis of AML with t(6;9) is independent of *FLT3* status.[94] Some studies suggest a role for monitoring of *DEK*::*NUP214* molecular status in management of the patient.[95]

Box 46-7 Acute Myeloid Leukemia With Other *KMT2A* Rearrangements

Acute Myeloid Leukemias (AMLs) With:

t(4;11)(q21.3;q23.3)/*AFF1*::*KMT2A*
t(6;11)(q27;q23.3)/*AFDN*::*KMT2A*
t(10;11)(p12.3;q23.3)/*MLLT10*::*KMT2A*
t(10;11)(q21.3;q23.3)/*TET1*::*KMT2A*
t(11;19)(q23.3;p13.1)/*KMT2A*::*ELL*
t(11;19)(q23.3;p13.3)/*KMT2A*::*MLLT1*

The differential diagnosis of AML with t(6;9)(p22.3;q34.1) includes blast transformation of chronic myeloid leukemia (CML) and rare AML with t(9;22)(q34.1;q11.2). Although the presence of basophilia is unusual in AML and is one clue to the diagnosis of AML with t(6;9)(p22.3;q34.1), basophilia is common in blast transformation of CML, and a prior history of CML is more suggestive of blast transformation than AML with t(6;9)(p22.3;q34.1). Basophilia may also be seen in the rare de novo AML with t(9;22)(q34.1;q11.2). Multilineage dysplasia appears to be less common in AML with t(9;22)(q34.1;q11.2), but this differential diagnosis is usually clarified only with cytogenetic studies.

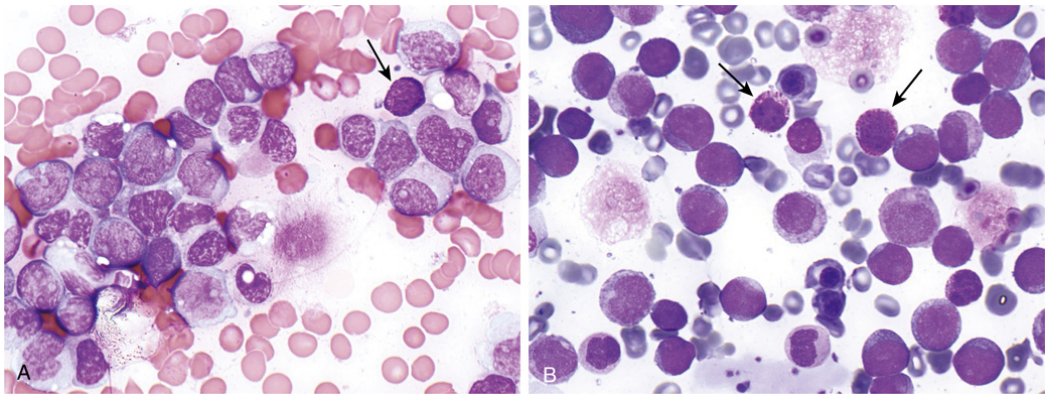

FIGURE 46-7 Acute myeloid leukemia with t(6;9)(p23;q34.1)/*DEK*::*NUP214*.Blast cells exhibit variable morphology but are often associated with admixed basophils *(arrows)*. **A,** Blasts with monocytic features. **B,** Myeloblasts without maturation and dysplastic erythroid precursors.

Box 46-8 Key Features of Acute Myeloid Leukemia With t(6;9)(p23;q34.1)/*DEK*::*NUP214*

- No specific blast cell morphology
- Often associated with erythroid hyperplasia and dysplasia
- Basophilia common
- Frequently associated with *FLT3* mutations
- Generally poor prognosis

Acute Myeloid Leukemia With inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2; MECOM (EVI1)*

AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2) occurs most commonly in adults, with only rare examples of this translocation reported in children, often in association with monosomy 7. The median age at diagnosis is 56 years, younger than the reported average of 63 years for adult AML in general. It represents 1% to 2% of AML in adults and may present de novo or after a history of MDS.[96-98] Most cases would have been classified as AML with multilineage dysplasia in the 2001 3rd ed. WHO classification and meet the criteria for a variety of morphologic AML types, other than APL. Patients typically are seen with anemia, and platelets may be normal or elevated, in contrast to the usual thrombocytopenia associated with other types of AML (**Box 46-9**). Some patients have hepatosplenomegaly. In addition to blasts, the peripheral blood may show dysplastic features, including hypogranular neutrophils with pseudo–Pelger-Huët nuclear morphology and large hypogranular platelets. Circulating megakaryocyte naked nuclei may be seen. The bone marrow blasts may show multiple morphologies, including myeloid blasts without differentiation, a mixture of myeloid and monocytic morphologies, and blasts with megakaryoblastic differentiation. Myeloperoxidase activity is often low. Megakaryocytes may be normal or increased in number, frequently with small nonlobated and bilobated forms or other dysplastic features. Dyserythropoiesis or dysmyelopoiesis is commonly present (**Fig. 46-8**). The core biopsy may show decreased cellularity and occasionally fibrosis. Flow cytometric studies in this disease are limited. Expression of CD34, CD13, CD33, and HLA-DR is typically described, with aberrant CD7 expression in some cases.[99-101] Cases with megakaryocytic differentiation may express CD41 and CD61.

Box 46-9 Key Features of Acute Myeloid Leukemia With inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2; MECOM*(EVI1)

- Mixture of blasts and monolobed or bilobed megakaryocytes
- Often associated with normal or elevated platelet counts
- Multilineage dysplasia common
- Generally poor prognosis

Chromosome 3q26.2 rearrangements may be cryptic on routine cytogenetic studies but detectable by FISH. The inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2) repositions a distal *GATA2* enhancer to activate *MECOM* expression. High expression of MECOM is a poor prognostic indicator independent of 3q26.2 translocations.[36] The translocation or inversion also simultaneously confers *GATA2* haploinsufficiency.[102,103] Secondary karyotypic abnormalities are reported in 75% of cases.[97] They are most commonly myelodysplasia-associated abnormalities, including −7, −5q, and complex aberrant karyotypes. Mutations of genes activating RAS/receptor tyrosine kinase signaling pathways are reported in 98% of cases with mutations of *NRAS* (27%), *PTPN11* (20%), *FLT3* (13%), *KRAS* (11%), *NF1* (9%), *CBL* (7%), and *KIT* (2%), and mutations of *GATA2* (15%), *RUNX1* (12%), and *SF3B1* (27%, often with *GATA2*) are also common.[104]

Patients with AML with inv(3) or t(3;3) have a poor prognosis, typically with short survival.[105,106] This poor prognosis appears to

be independent of *FLT3*-ITD status, although the data are limited by the rarity of this subtype. The presence of a complex karyotype or monosomy 7, however, appears to be associated with an even worse prognosis.[107] Age older than 60 years appears to be an independent risk factor for poor OS. Patients who can tolerate allogeneic hematopoietic cell transplantation may benefit from this therapy, but no survival advantage has been shown in some studies.[97,108] As in some patients with the t(6;9)(p23;q34) abnormality, some patients whose neoplastic cells have inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2) may be seen with less than 20% blasts. Such cases have been shown to have a similar prognosis, independent of blast cell count,[106] although response to traditional AML therapy appears to be poor in all groups.

The differential diagnosis of AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2) includes the megakaryoblastic type of AML, NOS; AML with t(1;22)(p13.3;q13.1); and myeloid proliferations of Down syndrome. The absence of Down syndrome obviously excludes the last possibility. The category of AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2) takes precedence over AML, NOS, so the karyotype resolves that differential diagnosis. The patient's age and karyotype are helpful in distinguishing AML with t(1;22)(p13.3;q13.1), which occurs in very young children, from AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2), which occurs primarily in adults.

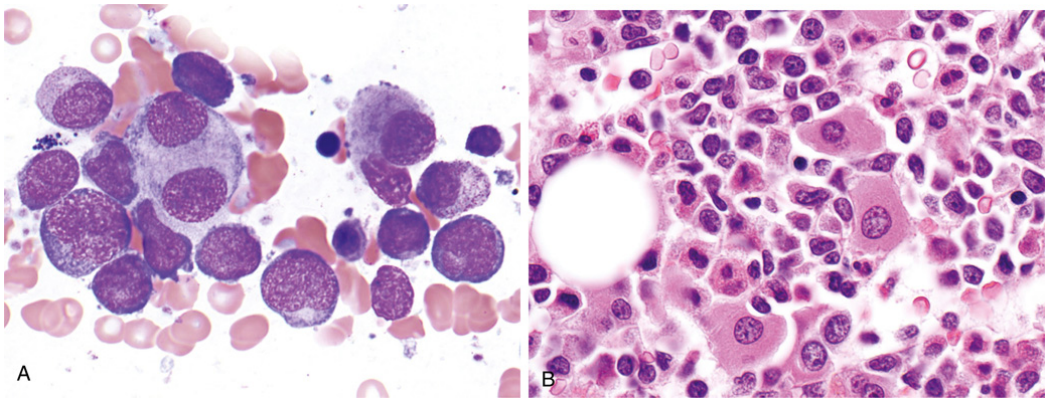

FIGURE 46-8 Acute myeloid leukemia with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)/*GATA2; **MECOM***.**A,** Increased blasts with monolobed and bilobed megakaryocytes are typical of this disorder. **B,** Distinctive hypolobated megakaryocytes are apparent on the biopsy specimen.

Acute Myeloid Leukemia With Other *MECOM* Rearrangements

MECOM is involved in other translocations in AML (see **Box 46-10**). These nonclassic *MECOM* rearrangements appear to present more commonly as MDS, often therapy-related, but may evolve to AML and have a similarly poor prognosis to the more classic *GATA2, MECOM* abnormalities. Although classic and nonclassic *MECOM* associated AMLs show similar mutation profiles, these nonclassic cases appear to be more commonly associated with complex karyotypes and chromosome 7 abnormalities.[109]

Acute Myeloid Leukemia With Other Rare Recurring Translocations

The ICC now includes a category to capture AML subtypes with rare recurring translocations, some of which were previous specific AML subtypes, such as AML with t(1;22)(p13.3;q13.1), or were captured by the prior category of AML with myelodysplasia-related changes, such as cases with t(3;5)(q25.3;q35.1). **Box 46-11** shows the different abnormalities included in this section, with many being more common in infants and children. The proposed WHO 5th ed. lists a similar category, but the specifics of what is included in the category remain unclear at the time that this chapter was prepared. In the ICC, cases in this category should be diagnosed as AML with the specific translocation listed rather than using "AML with rare recurring translocations" as the diagnosis. The specific features of the various types of AML in this category are variably described, but some have fairly distinctive clinical and pathologic features.

AML (megakaryoblastic) with t(1;22)(p13.3;q13.1)/*RBM15*::*MRTFA* (*MRTF1*/*MKL1*) is a rare form of AML presenting almost exclusively in infants and young children (less than 2.5 years).[110-112] The median age at diagnosis is 4 months, and 80% of cases are diagnosed in the first year of life. Some cases are congenital.[113] AML with t(1;22)(p13.3;q13.1) constitutes 1% or less of childhood AML and appears to be more common in girls. The clinical presentation commonly mimics a solid tumor, with hepatosplenomegaly or skeletal lesions (bilaterally symmetric periostitis and osteolytic lesions). Some cases present as myeloid sarcoma without evidence of marrow involvement. The complete blood count may show anemia and thrombocytopenia. Blasts in the blood or bone marrow exhibit typical features of megakaryoblasts, with a modest amount of agranular cytoplasm that may show blebs

or budding of platelets. The nuclear chromatin may be more condensed than myeloid blasts and is infrequently nucleolated (**Fig. 46-9**). The bone marrow aspirate may be hemodilute or aparticulate because of marrow fibrosis. Micromegakaryocytes are common, but multilineage dysplasia is not present. The bone marrow biopsy or biopsy of extramedullary involvement may show clumps of megakaryoblasts in fibrosis. Few cases have a reported flow cytometric immunophenotype. CD45 and CD34 may be negative, as in other AML with megakaryoblastic morphology. The myeloid antigens CD13 and CD33 are inconsistently expressed, as is HLA-DR. Immunoreactivity for megakaryocytic antigens CD41 and CD61 is commonly seen, and some cases may express CD56. Immunohistochemically, the cells are often negative for CD45, although they commonly express CD43. Other markers associated with megakaryocytic differentiation such as von Willebrand factor (factor VIII–related antigen) may be positive. Additional complex karyotypic abnormalities are common in "older" patients (older than 6 months). Mutations in *FLT3, NPM1, CEBPA,* and *WT1* are usually absent in AML with t(1;22)(p13.3;q13.1).[112] Although the role of the *RBM15:MRTFA* in leukemogenesis is still unclear, the fusion gene may modulate chromatin organization, *HOX*-induced differentiation, and extracellular signaling pathways, as well as confer an antiproliferative effect.[114,115]

Box 46-10 Acute Myeloid Leukemia With Other *MECOM* Rearrangements

Acute Myeloid Leukemias (AMLs) With:

- t(2;3)(p11~23;q26.2)/*MECOM*::*?*
- t(3;8)(q26.2;q24.2)/*MYC, MECOM*
- t(3;12)(q26.2;p13.2)/*ETV6*::*MECOM*
- t(3;21)(q26.2;q22.1)/*MECOM*::*RUNX1*

Diagnosis may be delayed in these patients owing to the difficulties described. The prognosis of AML with t(1;22)(p13.3;q13.1) is variable in the literature. Some studies suggested that patients respond well to intensive AML therapy[116]; however, others have found this to be a high-risk disease compared with other pediatric acute megakaryoblastic leukemias.[117,118]

The differential diagnosis of AML with t(1;22)(p13.3;q13.1) includes other AML with megakaryocytic features, including the myeloid proliferations of Down syndrome; these can be distinguished only by clinical history and karyotyping. However, multilineage dysplasia is usually present in other types of megakaryoblastic leukemias and is not seen in AML with t(1;22)(p13.3;q13.1). Though a Children's Oncology Group study found t(1;22)(p13.3q13.1) to be the most common recurring cytogenetic abnormality in pediatric acute megakaryocytic leukemia, the rare AML inv(16)(p13.3q24.3)/*CBFA2T3*::*GLIS2* and AMLs with *NUP98* translocations may also be of megakaryocytic lineage.[112] The differential diagnosis also includes other pediatric small, blue, round cell tumors. Biopsy of the marrow or extramedullary lesions of AML with t(1;22)(p13.3;q13.1) may show cohesive nests of small, blue, round cells, suggestive of a childhood solid tumor and leading to an erroneous diagnosis of neuroblastoma or hepatoblastoma in some cases. Especially in myeloid sarcoma cases, the diagnosis may not be

obvious until cytogenetic studies reveal the presence of t(1;22)(p13.3;q13.1).

* Occurs predominantly in infants and children.

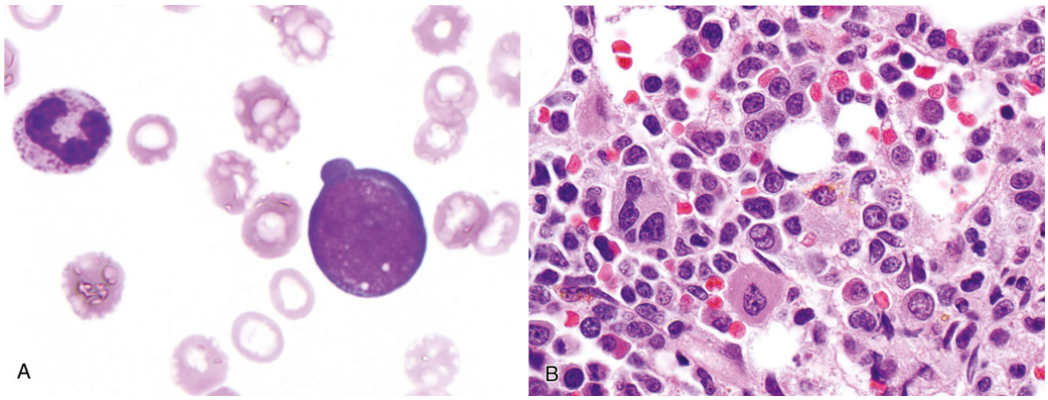

FIGURE 46-9 Acute myeloid leukemia (megakaryoblastic) with t(1;22)(p13.3;q13.1)/*RBM15*::*MRTF1*.**A,** Hemodilute aspirate shows rare blasts with basophilic cytoplasm and blebbing. **B,** Core biopsy shows blasts and atypical megakaryocytes.

AML with t(3;5)(q25.3;q35.1)/*NPM1*::*MLF1* is also a rare subtype that probably represents less than 1% of AML.[119,120] Myeloid proliferations with this cytogenetic abnormality may present as an MDS or as a number of morphologic AML subtypes. The AML cases were previously included in the category of AML with myelodysplasia-related changes of the revised WHO 4th ed. classification (**Fig. 46-10**). This AML type appears to be more common in young adult men than are other types of dysplasia-associated AMLs. It most cases, the t(3;5) is the sole cytogenetic abnormality, but very little is known about cooperating mutations in this disease. The translocation appears to result in cytoplasmic expression of the NPM protein, similar to AML with mutated *NPM1*,[121] but is a more aggressive disease. Interestingly, the translocation results in nuclear expression of the MLF1 protein, which is normally cytoplasmic, and this change appears to cause

instability in *TP53,* which might explain the more aggressive behavior of these rare cases compared with AML with mutated *NPM1*.[122] Patients tend to relapse early after therapy and may benefit from early hematopoietic cell transplantation.[123]

AML with t(8;16)(p11.2;p13.3)/*KAT6A*::*CREBBP* is most commonly associated with therapy-related disease, which is now designated separately as a qualifier. This AML type is associated with erythrophagocytosis and usually myelomonocytic or monocytic features (**Fig. 46-11**).[124-126] It occurs in both adults and children and may be congenital, de novo, or therapy related. Congenital cases are usually limited to the skin and may remit spontaneously during a few days.[127] Approximately 40% of cases are associated with disseminated intravascular coagulopathy[126] and may have increased promyelocytes, mimicking APL.[128] AML with t(8;16), therapy related, may occur after either alkylating agent or topoisomerase II inhibitor therapy and usually has a short latency period. Gene-expression profiling and microRNA pattern studies of this leukemia type have shown overexpression of RET and PRL and a unique pattern of HOX gene expression.[129,130] The overall prognosis of AML with t(8;16) is variable, but cases that arise after therapy have a poor prognosis.

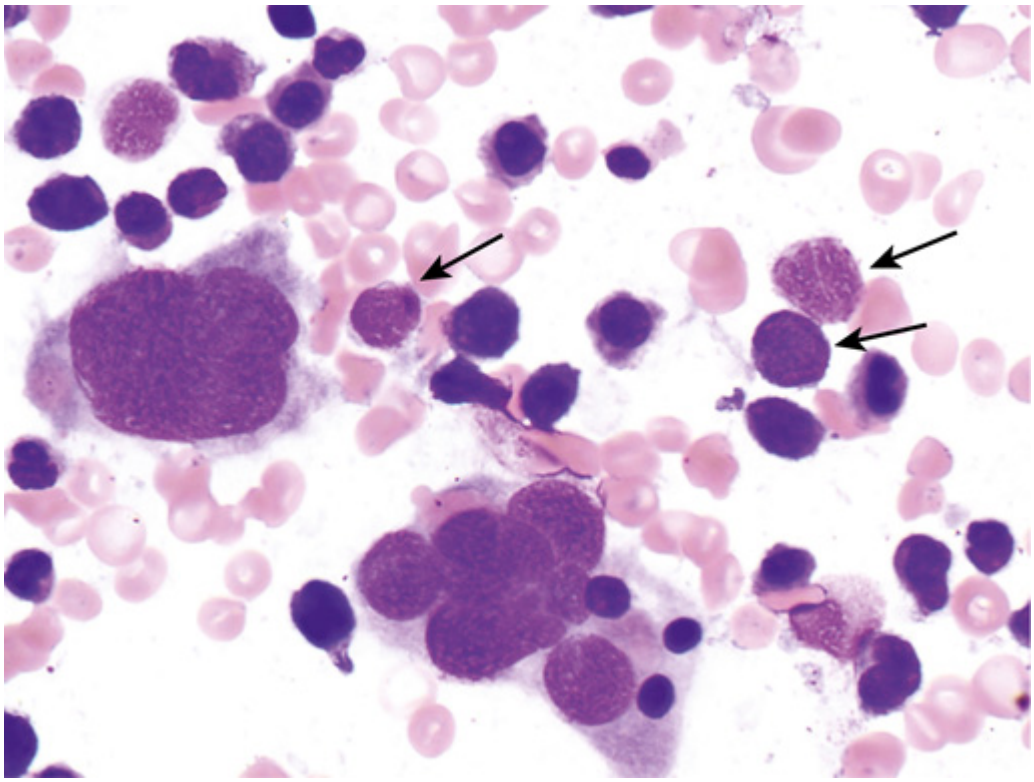

FIGURE 46-10 Acute myeloid leukemia with t(3;5)(q25.3;q35.1)/*MLF1*::*NPM1*.This disease is characterized by multilineage dysplasia. This example shows a florid erythroid hyperplasia constituting more than 50% of cells, with dysplastic megakaryocytes and scattered myeloblasts *(arrows)*. In the 4th ed. WHO classification (2008), the case would have met the criteria for erythroid leukemia (erythroid/myeloid type), with more than 20% of the nonerythroid cells being myeloblasts.

Acute Myeloid Leukemia With t(9;22)(q34.1;q11.2)/*BCR*::*ABL1*

Although most blast proliferations with a *BCR*::*ABL1* fusion, usually caused by t(9;22)(q34.1;q11.2), represent blast transformation of CML, ALL, or mixed-phenotype acute leukemia, rare cases of de novo AML with *BCR*::*ABL1* occur and are included as an entity in current classifications (**Box 46-12**). This AML type is rare, representing less than 1% of all cases, with a possible male predominance.[131-134] It is difficult to distinguish on an individual basis de novo AML with *BCR*::*ABL1* from myeloid blast transformation of CML, and exclusion of an occult chronic phase of CML preceding the diagnosis of AML, or after therapy for AML, is essential for diagnosis. Cases of de novo AML with *BCR*::*ABL1* appear to differ from blast crisis of CML by having less frequent splenomegaly and basophilia and slightly lower marrow cellularity. These cases fall into a variety of morphologic subtypes, other than APL. The average marrow cellularity in de novo cases is reported to be less than that typically seen in blast transformation of CML (80% versus 95%–100%), and dwarf megakaryocytes are reported to be less common in AML with *BCR*::*ABL1* compared with blast transformation of CML.[131,133,134] The immunophenotype of the blast cells in AML with *BCR*::*ABL1* is non-specific with expression of CD13, CD33, and CD34. Aberrant expression of CD19, CD7, and TdT is reportedly common.[131,133]

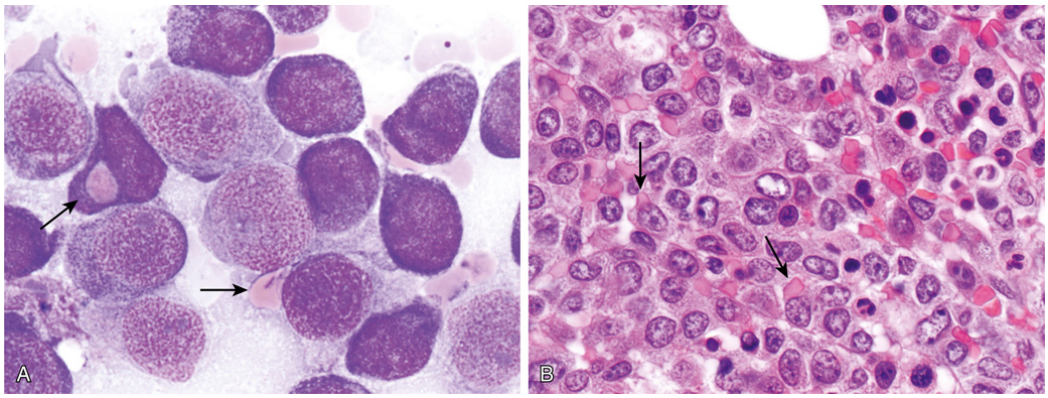

FIGURE 46-11 Acute myeloid leukemia with t(8;16)(p11.2;p13.3)/*KAT6A*::*CREBBP*.This disease is characterized by blasts showing erythrophagocytosis *(arrows),* which can be seen on aspirate smears **(A)** or biopsy sections **(B)**.

Although most cases demonstrate t(9;22)(q34.1;q11.2), the translocation may be cryptic. The *BCR*::*ABL1* fusion, usually the p210 transcript, is present in all cases. Most cases have additional cytogenetic abnormalities, including a complex karyotype, monosomy 7, or trisomy 8.[131,133,134] AML-associated mutations, particularly *NPM1* and *FLT3*-ITD, are reported in AML with *BCR*::*ABL1* but not in blast transformation of CML, but these mutations are relatively uncommon.[134] Loss of *IKZF1* and *CDKN2A* in AML with *BCR*::*ABL1* and cryptic deletions within the IGH and TRG genes have been described as useful in differentiating de novo AML from myeloid blast transformation of CML, but such testing is not routinely available and has not been validated in multiple laboratories.[135]

Although rare, AML with *BCR*::*ABL1* appears to demonstrate a poor response to traditional AML therapy or to tyrosine kinase inhibitor therapy alone.[131] However, survival may be improved with

tyrosine kinase inhibitor therapy followed by allogeneic hematopoietic cell transplantation.[136-139]

Box 46-12 Key Features of Acute Myeloid Leukemia t(9;22)(q34.1;q11.2)/*BCR*::*ABL1*

- Must be distinguished from myeloid blast crisis of chronic myeloid leukemia
- May benefit from tyrosine kinase inhibitor therapy and hematopoietic cell transplantation

Acute Myeloid Leukemia With Mutated *NPM1*

AML with mutated *NPM1* shows a female predominance and is found in approximately 50% of adult AML with a normal karyotype and 20% of pediatric AML with a normal karyotype.[140-144] *NPM1* mutations of exon 12 are best detected by PCR or NGS, but identification of cytoplasmic dislocation of *NPM1* by immunohistochemistry may be useful as a surrogate method for detecting this gene mutation. The immunohistochemical approach has been improved in recent years with the development of mutant-specific antibodies that make interpretation easier. Approximately 40% of *NPM1*-mutated patients are also positive for *FLT3*-ITD mutations. In the absence of an *FLT3*-ITD mutation, *NPM1* mutation in cytogenetically normal AML is associated with a favorable prognosis, similar to that of core binding factor leukemias. The presence of *FLT3*-ITD mutations appears to abrogate that effect, and for that reason, mutations of both genes must be studied and the use

of large NGS gene panels has become routine for the diagnosis. *NPM1* mutations are only rarely reported in association with other disease-defining recurring cytogenetic abnormalities.

In adults, the majority of *NPM1*-mutated AML cases show monocytic differentiation, often with "cup-shaped" or "fish-mouth" nuclear indentations. In children, *NPM1*-mutated cases most commonly show myeloid blasts with or without differentiation or show myelomonocytic differentiation. Rare cases of erythroleukemia with *NPM1* mutation are described in children. Adult cases of AML with mutated *NPM1* are predominantly CD34 negative. Among cases with nonmonocytic morphology are those demonstrating cuplike nuclear invaginations and lacking CD34 and HLA-DR expression (see **Fig. 46-2**).[145,146] Approximately one-quarter of cases of de novo AML with mutated *NPM1* demonstrate multilineage dysplasia, despite usually having a normal karyotype. Such cases were considered AML-MRC in the 2008 4th ed. WHO classification, but the presence of dyspoiesis in this setting does not appear to affect prognosis,[147,148] and such findings no longer affect the diagnosis in current classifications. This AML type is characterized by high CD33 expression; common expression of CD117, CD123, and CD110; and often low CD13 expression.[149] HLA-DR is often negative. AML with mutated *NPM1* may have an immature myeloid immunophenotype or a monocytic immunophenotype (positive for CD36, CD64, CD14).[150] Although less common, CD34-positive cases occur and have been associated with worse prognosis.[151,152]

The *NPM1* gene at chromosome 5q35.1 encodes a molecular chaperone, shuttling molecules from the nucleus to the cytoplasm; in addition, it plays multiple other roles, including ribosome biogenesis,

centrosomal duplication, and regulation of the ARF-TP53 tumor suppressor pathway.[153,154] Mutations in exon 12 affect the amino acid composition of the nucleophosmin C terminus; this creates a nuclear export motif, with resultant dislocation of nucleophosmin to the cytoplasm. *NPM1* is a chromosomal translocation partner in various types of leukemia and lymphoma in which the aberrantly regulated product appears to be oncogenic. The native product apparently has both oncogenic and tumor suppressor capabilities. *NPM1* is typically located in nucleoli. In patients with *NPM1* mutations, the aberrantly localized mutant nucleophosmin can be identified in the blast cytoplasm by immunohistochemistry. However, the mutation status of *NPM1* with other gene mutations, including *FLT3*-ITD, *DNMT3A, IDH1, KRAS/NRAS,* and cohesin complex genes are relatively common,[23] and should be assessed. Of AMLs with mutated *NPM1,* 5% to 15% show chromosomal aberrations, including +8 and del(9q).[155] These karyotype abnormalities appear to not affect prognosis.

Whereas *NPM1* mutation is a disease-defining lesion in the appropriate clinical and pathologic setting, it frequently represents a later event in leukemogenesis, commonly secondary to mutations in epigenetic modifiers, such as *DNMT3A, TET2, IDH1,* and *IDH2*.[27,28,156] AML with mutated *NPM1* shows a distinct gene-expression profile characterized by upregulation of *HOX* genes[157,158] that differs from that of other AML types, including AML with *KMT2A* translocations.[159] *NPM1*-mutated AML is also characterized by a unique microRNA signature.[160]

NPM1 mutations may occur as a late event in CMML and may portend more rapid transformation to acute leukemia,[41] but in the

ICC such cases should be diagnosed as CMML whenever they fulfill the diagnostic criteria for such entity. The ICC requires a blast count of at least 10% in an *NPM1* mutated case before diagnosing AML, while the proposed WHO 5th ed. classification does not appear to have a blast cell count requirement for such a diagnosis.

AML with mutated *NPM1* has a generally favorable prognosis in the absence of *FLT3*-ITD mutations. However, the combination of *NPM1, FLT3*-ITD, and *DNMT3A* mutations in individual cases is associated with a particularly poor outcome.[161]

Acute Myeloid Leukemia With In-Frame bZIP *CEBPA* Mutations

CEBPA is a tumor suppressor gene located on chromosome 19q13.1 that encodes a differentiation-inducing transcription factor involved in granulocytic differentiation and diverse programs such as lung development, adipogenesis, and glucose metabolism.[162] *CEBPA* may be inactivated through multiple mechanisms, including transcriptional repression by the RUNX1::RUNX1T1 fusion protein of t(8;21) AML and epigenetic modification. Point mutations of *CEBPA* are detected in 13% of cytogenetically normal AML in adults and in 17% to 20% of cytogenetically normal AML in children.[163-165] It was initially thought that any mutation in *CEBPA* and later only biallelic mutations of the gene were prognostically significant.[166-170] More than 100 different nonsilent mutations have been described. This range of mutation sites made routine testing for this mutation more complicated, but the assay has become more widely available. Mutations commonly lead to synthesis of a smaller dominant negative isoform that inhibits wild-type protein function. Unlike the

common association between *NPM1* and *FLT3*-ITD mutations, *FLT3* abnormalities are relatively uncommon in AML with *CEBPA* mutations. With more in-depth study, it is now understood that the prognostic significance of *CEBPA* mutations in AML relates to the presence of in-frame bZIP mutations of the gene.[171-173] AML with in-frame bZIP *CEBPA* mutations has a favorable prognosis, and patients are unlikely to benefit from allogeneic hematopoietic cell transplantation.

The morphologic subtypes of myeloblasts in AML with in-frame bZIP *CEBPA* mutations are most commonly AML with or without differentiation. AML with myelomonocytic or monocytic differentiation is less commonly seen, and erythroleukemia or megakaryoblastic leukemia has not been described. *CEBPA* mutations are rarely described in therapy-related AML. Similar to AML with mutated *NPM1,* as many as 26% of AML cases with *CEBPA* mutations may have multilineage dysplasia,[174] which does not affect the prognosis or diagnosis. There is no specific immunophenotype for the blasts in AML with mutations of *CEBPA,* but the myeloblasts frequently show aberrant expression of CD7 without other T-lineage–associated markers.[175,176] More than 70% of AMLs with mutations of *CEBPA* have a normal karyotype. Approximately 10% have a single karyotypic abnormality, and only rare cases have a complex karyotype. *FLT3*-ITD mutations occur in 5% to 9% of cases and *GATA2* mutations in 39% of cases.[177,178]

Germline mutations of *CEBPA* may also occur and are associated with a familial syndrome.[15] For this reason, consideration of screening of germline DNA and family members may be indicated

once a diagnosis of AML with in-frame bZIP *CEBPA* mutations is made.

The diagnosis of AML with *CEBPA* mutations differs between the ICC and proposed WHO 5th ed. classification. The ICC allows only in-frame bZIP mutations for the diagnosis and allows for a diagnosis of AML when 10% or more blasts are present in the bone marrow or peripheral blood. The WHO appears to allow for either bZIP or biallelic mutations, and also requires a blast count of 20% or more for a diagnosis of AML.

Acute Myeloid Leukemia and Myelodysplastic Syndrome/Acute Myeloid Leukemia With Mutated *TP53*

The ICC introduced the new category of AML and MDS/AML with mutated TP53 with, as previously mentioned, AML defined by 20% or more peripheral blood or bone marrow blasts and the new category of MDS/AML defined by 10% to 19% peripheral blood or bone marrow blasts. Mutations of *TP53* in AML are usually associated with a complex karyotype and confer an even worse prognosis in such cases compared with AML with a complex karyotype and no *TP53* mutation.[25,179-181] For this reason, the new category was created with most such cases falling in the prior WHO categories of AML with myelodysplasia-related changes, therapy-related myeloid neoplasms, or pure erythroid leukemia. The former two categories are eliminated in the ICC.

Alterations of *TP53* are complex and include gene deletions, loss of heterozygosity, and single nucleotide and insertion/deletion mutations.[182] Most *TP53* mutations in AML are missense mutations

that involve the DNA-binding domain (DBD).[183] Mutant premature termination codons and frameshift mutations result in strong disruption of TP53 function, whereas the effect of mutations resulting in a single amino-acid substitution or deletion is dependent on their position within the DBD. The frequency of *TP53* mutations in AML is approximately 10% but is increased in certain subpopulations such as those with AML after MDS or MDS/MPN, therapy-related AML, or pure erythroid leukemia.[184-187] *TP53* mutation is in the adverse prognostic group of the 2022 European LeukemiaNet (ELN) classification[188] with *TP53*-mutated AML having a particularly poor prognosis compared with the rest of the AML in this group.[189] The dismal effect of *TP53* mutations on patient outcome appears to transcend blast count with equally poor outcomes in patients presenting as MDS or AML, and whether the disease is therapy-related or clinically de novo.[190]

The prognosis of AML and MDS with mutated *TP53* varies, somewhat, when monoallelic versus biallelic mutations are compared; biallelic mutations, which are the typical type identified in AML, are associated with a worse prognosis. Despite this, the poor prognosis of AML with monoallelic *TP53* mutations remains significant, and the ICC allows for a case to be classified as AML or MDS/AML with either allelic type if the variant allele frequency is ≥10%. Some studies have found a higher *TP53* VAF (>40%) to be associated with shorter survival in AML, while other studies have not.[179,180]

Immunohistochemistry for TP53 protein expression can be used as a screening test for this category but is not adequate alone. Each laboratory must optimize the stain for decalcified bone marrow

biopsies to reduce false negative results, but even with an optimized assay, false positive and false negative results may occur.[191] Therefore, the category is defined by the molecular detection of a *TP53* mutation.

As mentioned, most cases of AML with mutated *TP53* demonstrate features of pure erythroid leukemia, or of the prior categories of AML with myelodysplasia-related changes or therapy-related myeloid neoplasms. Most cases demonstrate multilineage dysplasia (**Fig. 46-12**). Cases meeting prior criteria for pure erythroid leukemia have at least two *TP53* abnormalities (both mutations and aberrant or deleted chromosome 17p) in over 90% of cases,[186] and these cases should now be classified as AML with mutated *TP53* with a note that they represent the pure erythroid leukemia type. Cases now diagnosed as MDS/AML with mutated *TP53* based on 10% to 19% blast cells in the blood or marrow would have been previously diagnosed as MDS with excess blasts-2 (MDS-EB-2) or therapy-related myeloid neoplasm in the revised WHO 4th ed. classification. In addition to *TP53* mutations, AML and MDS/AML cases often have co-existing myelodysplasia-related cytogenetic abnormalities, including complex karyotypes. Despite the presence of a category of AML or MDS/AML with myelodysplasia-related cytogenetic abnormalities in the ICC, the presence of a *TP53* mutation takes diagnostic precedence over those cytogenetic abnormalities.

The proposed WHO 5th ed. does not include a category of AML with mutated *TP53* but does include a category of MDS with mutated *TP53* that would overlap with the ICC disease MDS/AML with mutated *TP53*. In the proposed WHO 5th ed. classification, ICC AML with mutated *TP53* cases (having 20% or more blasts) would most

commonly fall into the more general category of AML, myelodysplasia-related based on co-existing myelodysplasia-related cytogenetic abnormalities. Such categorization, however, fails to highlight the extremely poor prognosis of the *TP53* mutated group. The diagnostic criteria for the proposed WHO 5th ed. category of MDS with mutated *TP53* differ from the ICC category MDS/AML with mutated *TP53* (having 10%–19% blasts) in that the ICC allows for monoallelic or biallelic mutations while the proposed WHO category requires the mutations be biallelic.

Acute Myeloid Leukemia and Myelodysplastic Syndrome/Acute Myeloid Leukemia With Myelodysplasia-Related Gene Mutations

As mentioned, the prior WHO category of AML with myelodysplasia-related changes has been eliminated in the ICC and replaced by several categories, particularly AML with mutated *TP53,* AML with myelodysplasia-related gene mutations, and AML with myelodysplasia-related cytogenetic abnormalities; similar categories with these features have also been added to the MDS/AML group. The proposed WHO 5th ed. classification also modified the prior category of AML with myelodysplasia-related changes, now renamed AML, myelodysplasia-related, and both ICC and the WHO eliminate cases from these categories based on the presence of morphology (multilineage dysplasia) alone.

Although multilineage dysplasia in AML is associated with a poor prognosis,[20,192] it has become clear that some genetic abnormalities, such as mutated *NPM1,*[148] take precedence over this finding and that

other genetic abnormalities are better predictors of prognosis than the morphologic changes.

Several studies have evaluated cases of myelodysplasia-related AML or AML arising after prior MDS or prior therapy and identified clusters of gene mutations associated with those changes.[29-31,193] These genetic abnormalities, which vary somewhat among studies, have been termed "secondary" or "spliceosome" type mutations. When these mutations were found among AML cohorts without recurring genetic abnormalities, prior therapy, or MDS (generally corresponding to cases of AML, NOS in prior classifications), their presence remained predictive of a poor prognosis. For this reason, both the ICC and revised WHO 5th ed. classification adopted similar, but not identical, gene lists in which the presence of any one of those genes places the case in this new category. In the ICC, a patient with 10% or more peripheral blood or marrow blasts and any one of these gene mutations (*ASXL1, BCOR, EZH2, RUNX1, SF3B1, SRSF2, STAG2, U2AF1,* or *ZRSR2*) is diagnosed as AML or MDS/AML with myelodysplasia-related gene mutations based on the blast cell count (AML if 20% or more and MDS/AML if 10%–19%). Many such cases will have multilineage dysplasia (**Fig. 46-13**) or myelodysplasia-related cytogenetic abnormalities in addition to the gene mutation, but the new ICC mutation category takes precedence over the morphologic and cytogenetic abnormalities. In addition to overlapping with the prior WHO category of AML with myelodysplasia-related changes, this category replaces the prior provision entity in the revised WHO 4th ed. classification of AML with mutated *RUNX1*. The proposed WHO 5th ed. classification includes a similar gene list as one pathway for the diagnosis of AML,

myelodysplasia-related, but the proposed WHO gene mutation list does not include *RUNX1* (**Table 46-1**). AML with mutated *RUNX1* is entirely eliminated in the proposed WHO 5th ed. classification. Also, cases in this category diagnosed as MDS/AML with myelodysplasia-related gene mutations by ICC would be classified as MDS with increased blasts 2 (MDS-IB-2) in the proposed WHO 5th ed. classification.

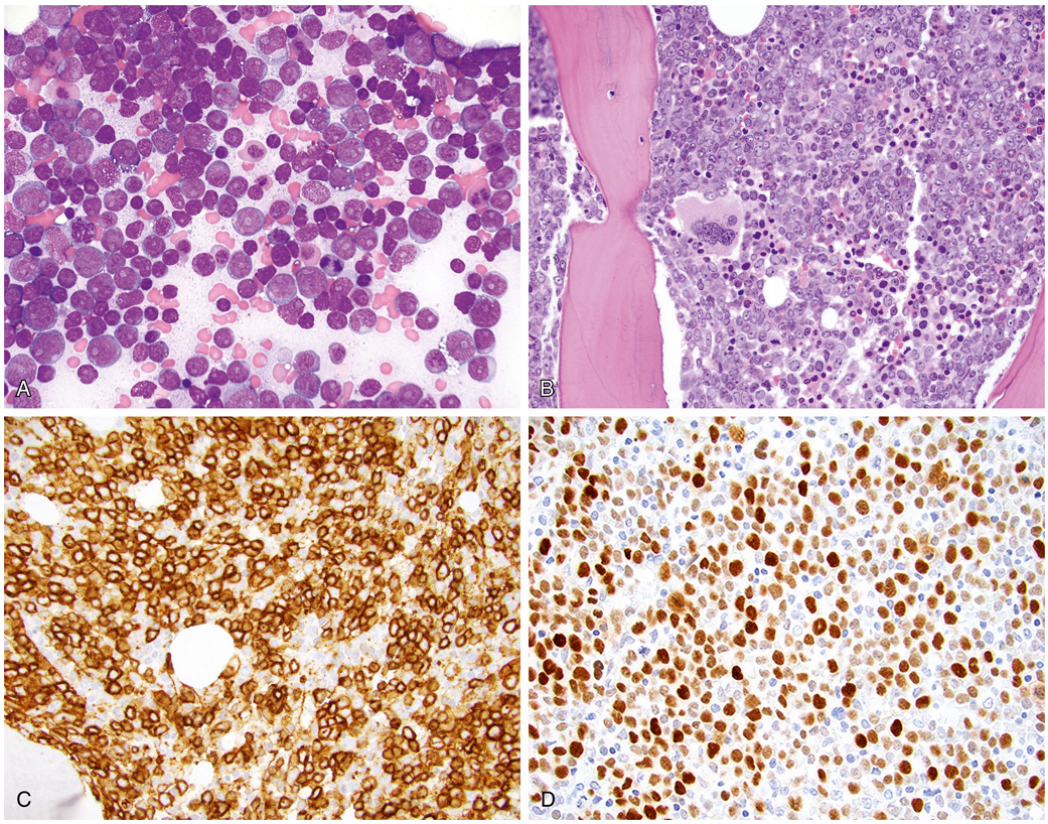

FIGURE 46-12 Acute myeloid leukemia with mutated *TP53*.**A,** The aspirate demonstrates a blast cell proliferation with admixed dysplastic erythroid precursors and immature erythroid cells. **B,** The biopsy shows sheets of immature cells with admixed maturing erythroid cells. Atypical megakaryocytes were also present. The cells express CD34 **(C)** with nuclear expression of TP53 **(D)**. The case had a complex karyotype and a *TP53* mutation, meeting criteria for acute myeloid leukemia with mutated *TP53*.

Acute Myeloid Leukemia and Myelodysplastic Syndrome/Acute Myeloid Leukemia With

Myelodysplasia-Related Cytogenetic Abnormalities

The final MDS-related AML category of the ICC is AML and MDS/AML with myelodysplasia-related cytogenetic abnormalities. MDS-related cytogenetic abnormalities have been a pathway to making a diagnosis of AML with myelodysplasia-related changes in the WHO 4th ed. and revised 4th ed. classification,[11,40] but the ICC reduces the number of cytogenetic abnormalities that fall into this category (see **Table 46-2**).[12] Specifically, balance cytogenetic translocations previously listed in this group are largely moved to the category of AML with other rare recurring translocations (see **Box 46-11**) and monosomy 13 or 13q deletions are no longer included because of a lack of prognostic significance. Though the presence of trisomy 8 or del(20q) are not sufficient to make a diagnosis of MDS without a blast cell increase, their presence in cases with 10% or more blasts (MDS/AML and AML) are predictors of a poor prognosis, and these two abnormalities have been added to the ICC list of MDS-related cytogenetic abnormalities. Like AML and MDS/AML with myelodysplasia-related gene mutations, these cases frequently evolve from prior MDS, may be therapy related and are often associated with multilineage dysplasia (**Fig. 46-13**). There is also overlap between MDS-related cytogenetic abnormalities, *TP53* mutations, and MDS-related gene mutations, but these later categories take diagnostic priority over the category of AML and MDS/AML with myelodysplasia-related cytogenetic abnormalities.

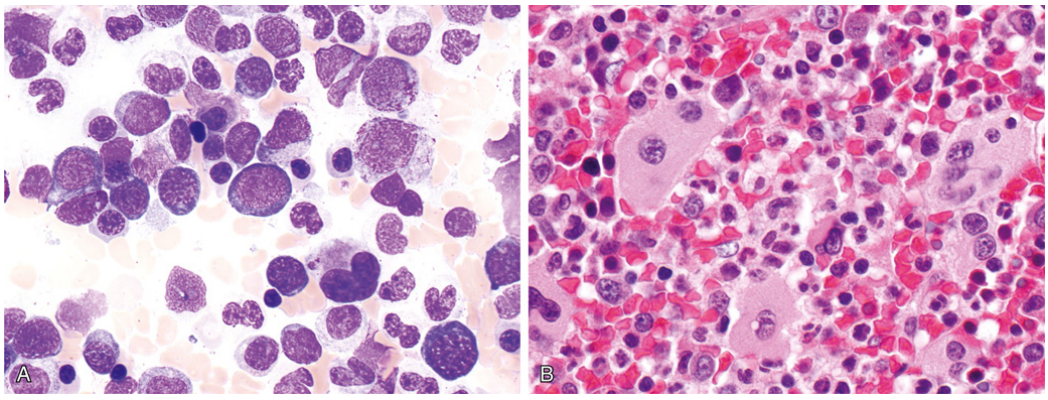

FIGURE 46-13 Background dysplasia in acute myeloid leukemia.Though multilineage dysplasia is no longer a diagnostic criterion for a specific acute myeloid leukemia (AML) subtype, it is common in AML with mutated *TP53*, AML with myelodysplasia-related gene mutations, AML with myelodysplasia-related cytogenetic abnormalities, and therapy-related AMLs. Dysplastic changes are best seen on aspirate smears **(A)**, but dysplastic megakaryocytes are often apparent on biopsy sections **(B)**. On the aspirate smear **(A)**, note the hypogranular neutrophils with abnormal nuclear lobation, erythroid precursors with irregular nuclear contours, and small hypolobated megakaryocytes with admixed blast cells.

ICC, International Consensus Classification; *WHO,* World Health Organization.

* Considered definitional in the absence of a mutation in *TP53* or a myelodysplasia-related gene mutation (see **Table 46-1**).

† Three or more unrelated abnormalities, none of which is included as an acute myeloid leukemia specific genetic abnormality in the classifications (such cases should be classified in the appropriate cytogenetic group).

Most cases of the ICC category of AML with myelodysplasia-related cytogenetic abnormalities (defined as having 20% or more peripheral blood or bone marrow blasts) would be included in the proposed WHO 5th ed. classification as AML, myelodysplasia related, but the WHO continues to include cases with monosomy 13 or 13q deletions in this category and does not include cases with +8 or del(20q). Cases of ICC MDS/AML with myelodysplasia-related cytogenetic abnormalities would be classified as MDS with increased blasts 2 (MDS-IB-2) in the proposed WHO 5th ed. classification.

Acute Myeloid Leukemia and Myelodysplastic Syndrome/Acute Myeloid Leukemia, Not Otherwise Specified

Cases with 10% or more peripheral blood or bone marrow blasts that do not fulfill the definition of AML or MDS/AML in any of the prior categories or myeloid neoplasms of Down syndrome are considered AML or MDS/AML, NOS, with AML used for those with 20% or more blasts and MDS/AML for those with 10% to 19% blasts. There are a number of subtypes of AML, NOS that have been used in prior

WHO classifications, but these lack the cytogenetic or clinical features that would warrant calling them specific disease types, and they should be considered morphologic subtypes if the reader wishes to subclassify them.[20,194,195] Morphologic subclassification is not essential. The exceptions to this might include pure erythroid leukemia and acute panmyelosis with myelofibrosis (APMF), which are defined by different criteria, but cases belonging to those categories have become extraordinarily rare because of the larger number of cytogenetic and molecular genetic diagnostic qualifiers that take diagnostic precedence in both settings.

Most of the morphologic subtypes of AML, NOS are defined by previous FAB criteria,[2] but their blast thresholds reflect lower blast cell counts than originally proposed by FAB. Because flow cytometric immunophenotyping is routine in modern practice, cytochemical studies are not required for the subtyping of AML, NOS, although they may provide helpful information in selected cases.

This category continues to shrink in terms of percentage of cases as the genetic categories of AML and MDS/AML expand and there are really no data on the genetic characteristics of this group as genetic disease subtypes fall into the other disease categories in both the ICC and proposed WHO 5th ed. classification.

In general, this ICC category of AML, NOS corresponds to AML, defined by differentiation in the proposed WHO 5th ed., while cases of ICC MDS/AML NOS would generally be diagnosed as MDS-EB-2. These sections describe the historic features of the AML, NOS subtypes. It is difficult to use these criteria for MDS/AML cases, and a diagnosis of MDS/AML, NOS is suggested rather than attempting to subclassify such cases with AML, NOS criteria.

Acute Myeloid Leukemia With Minimal Differentiation

AML with minimal differentiation have 20% or more peripheral blood or marrow blasts that lack definitive cytologic and cytochemical evidence of myeloid lineage but demonstrate immunophenotypic evidence of myeloid lineage. The blasts lack granules or Auer rods and may be confused with lymphoblasts. The blasts are cytochemically negative for myeloperoxidase or Sudan black B (<3% positive) and are non-specific esterase negative (<20%), but they may show immunophenotypic evidence of myeloperoxidase expression. By flow cytometry, blasts express CD34, CD38, and HLA-DR. They commonly express CD13, CD33, or CD117. The blasts usually lack expression of monocytic or myeloid antigens, such as CD15, CD11b, CD14, or CD64. Expression of CD7, CD19, and TdT may be present, but blasts are negative for the more definitive B-lymphoid and T-lymphoid–associated cytoplasmic antigens CD79a, CD22, and CD3.

Acute Myeloid Leukemia Without Maturation

AML without maturation is defined as a peripheral blood or bone marrow blast population of 20% or more that is cytochemically positive for myeloperoxidase or Sudan black B and negative (<20%) for non-specific esterase. In addition, blasts must constitute 90% or more of the nonerythroid marrow cells. Blasts usually have sparse granules and infrequent Auer rods, although the identification of these features does not preclude this diagnosis. Cases may be mistaken for lymphoblastic proliferations without immunophenotyping or cytochemical studies. Blasts express

myeloid-associated antigens, but there is no specific immunophenotypic profile.

Acute Myeloid Leukemia With Maturation

AML with maturation is probably the most common morphologic type of AML, NOS. It has cytochemical features identical to those of AML without maturation; however, it differs by having more than 10% of nonerythroid marrow cells showing maturation to the promyelocyte or later stage of differentiation. Blasts more frequently contain cytoplasmic granules or Auer rods but exhibit no specific cytogenetic abnormalities or immunophenotypic profile.

Acute Myelomonocytic Leukemia

In acute myelomonocytic leukemia, the sum of myeloblasts, monoblasts, and promonocytes is 20% or more. Of the leukemic cells, 20% to 79% are of monocyte lineage, often demonstrated by reactivity with the non-specific esterase stain; however, cytochemical studies are not necessary for diagnosis when the morphologic identity of the monocyte lineage is obvious. Numerous monocytes may be present in the peripheral blood and may mimic MDS/MPN, especially CMML. Both granulocytic and monocytic differentiation are observed in varying proportions in the bone marrow. The major criterion distinguishing acute myelomonocytic leukemia from AML with maturation is the proportion of neoplastic cells with monocytic features, which collectively must equal 20% or more of the blasts. The immunophenotype of acute myelomonocytic leukemia generally reflects the dual differentiation pattern of the leukemic cells, with some populations expressing fairly typical myeloid antigens and

others expressing more monocytic antigens, including CD14 and CD64.

Careful distinction of promonocytes from abnormal monocytes in the bone marrow is essential to separate acute myelomonocytic leukemia from CMML.[196] Promonocytes retain fine chromatin, indistinct nucleoli, and delicate nuclear folds, reflecting their immaturity. In contrast, abnormal immature-appearing monocytes of CMML have more condensed chromatin and generally more folded or convoluted nuclear contours. In a new diagnosis, the distinction between CMML and acute myelomonocytic leukemia may not be possible with a peripheral blood smear. Correlation with bone marrow findings is essential to resolve the diagnosis because the immature populations of acute myelomonocytic leukemia are more readily identified in marrow. A reliable discriminating immunophenotype is not available because promonocytes typically lack CD34.

Acute Monoblastic and Monocytic Leukemias

Acute monoblastic and monocytic leukemias have 20% or more immature cells (blasts or promonocytes) in peripheral blood or bone marrow, and 80% or more of the marrow cells have monocytic features by morphology (**Fig. 46-14**), cytochemistry, or immunophenotyping studies. Cases can be further subdivided by the maturity of the monocytic cells. If 80% or more of the blasts are poorly differentiated (monoblasts), the case is considered acute monoblastic leukemia; if the monoblasts are less than 80% and the cells show promonocytic and monocytic features, it is considered acute monocytic leukemia. Monoblasts are large and have

moderately abundant, variably basophilic cytoplasm, which frequently contains delicate peroxidase-negative azurophilic granules or vacuoles. Auer rods are not observed. The nucleus is round, with reticular chromatin and one or more prominent nucleoli. Monoblasts are non-specific esterase positive and myeloperoxidase negative. When the leukemic cells manifest more obvious cytologic evidence of monocytic differentiation and maturation, they are called *promonocytes*. These cells are considered to be blast equivalent and for diagnostic purposes are counted as blasts. Their nucleus has delicate chromatin and a characteristic folded or cerebriform appearance. The cytoplasm is less basophilic than that of monoblasts and contains a variable number of azurophilic granules. The promonocytes are usually non-specific esterase positive; some exhibit weak myeloperoxidase activity.

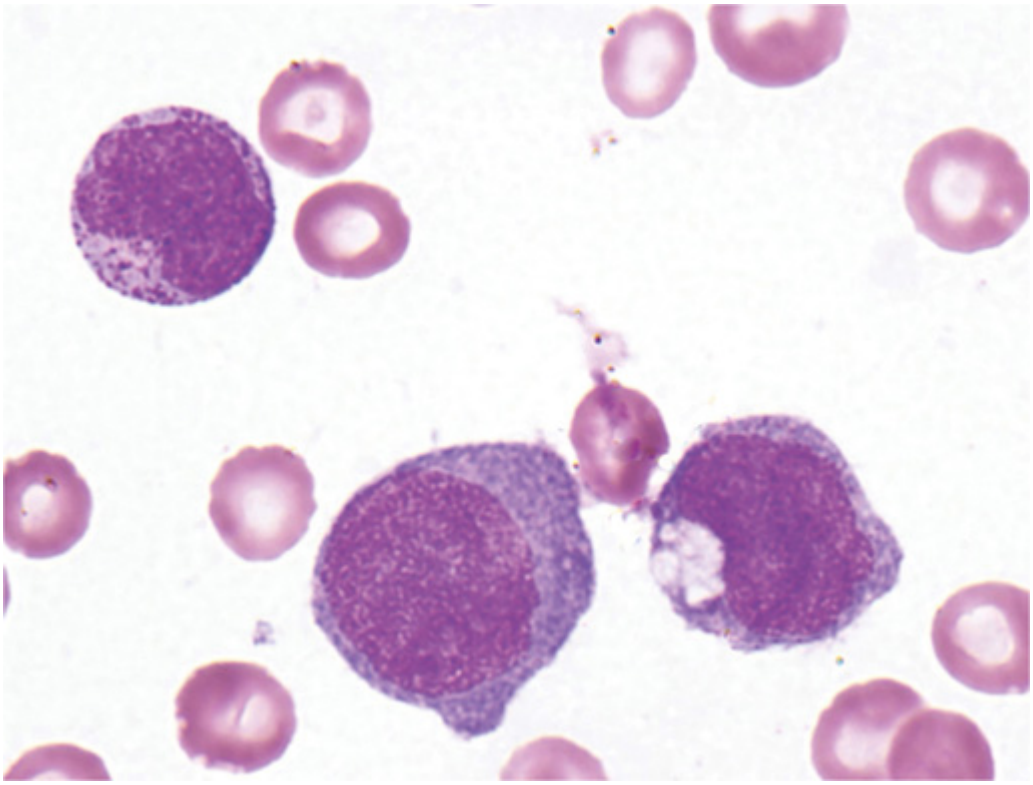

FIGURE 46-14 Acute monocytic leukemia (AML, NOS).Blasts may have round or more monocytoid folded nuclei and cytoplasmic vacuoles. The leukemia demonstrated no recurring genetic abnormality or defining gene mutations and meets criteria for acute myeloid leukemia, not otherwise specified.

The immunophenotype of acute monoblastic and monocytic leukemia is characterized by the expression of monocytic differentiation antigens, but the patterns of expression vary. Both subtypes often lack CD34 but may express CD117. They commonly express HLA-DR, CD13, and bright CD33, with CD15 and CD65. Typically, at least two markers of monocytic differentiation are present, including CD14, CD4, CD11b, CD11c, CD64, CD68, CD36,

lysozyme, and CD163. Aberrant expression of CD7 and CD56 is not unusual. Myeloperoxidase may be weakly positive in acute monocytic leukemia. Immunohistochemistry may show positivity for CD68 and lysozyme, but these are relatively non-specific. CD163 appears to be a more specific marker for monocyte lineage, but it may be less sensitive.

Monoblastic and monocytic leukemias are associated with a high incidence of organomegaly, lymphadenopathy, and other tissue infiltration. In a significant number of cases, the first clinical manifestations of leukemia result from extramedullary tissue infiltrates. Despite these seemingly unique clinical features, a diagnosis of acute monoblastic or acute monocytic leukemia does not confer prognostic significance.[194]

Pure Erythroid Leukemia

Pure erythroid leukemia is composed predominantly of erythroid cells and differs from other AML types by having no increase in myeloblasts. Two subtypes of erythroid leukemia were historically recognized and were included in the 2008 4th ed. WHO classification, but only one, pure erythroid leukemia, is currently recognized.[197]

The prior erythroid/myeloid leukemia has been eliminated as an AML, NOS subtype; by definition, 50% or more of all nucleated bone marrow cells were erythroid precursors, and 20% or more of the remaining cells (nonerythroid) were myeloblasts. Such cases would now be classified as MDS if blasts are below 10% and most as MDS/AML with mutated *TP53,* MDS/AML with myelodysplasia-

related gene mutations, or MDS/AML with myelodysplasia-related cytogenetic abnormalities if blasts are 10% to 19%.

In pure erythroid leukemia, the erythroid lineage is the only obvious component of acute leukemia; no significant myeloblast component is apparent. The neoplastic cells are predominantly or exclusively pronormoblasts and early basophilic normoblasts. These cells must constitute over 80% of the marrow elements, with at least 30% of cells being proerythroblasts. The erythroblasts are commonly CD34 negative and HLA-DR negative by flow cytometry and lack expression of myeloid-associated antigens. The more mature forms express hemoglobin A and glycophorin. The more immature erythroid progenitors may be CD36 positive. Some cases may also express megakaryocytic markers, such as CD41 and CD61, and it may not be possible to distinguish such cases as having an erythroid or a megakaryocytic lineage.[198] E-cadherin staining may be useful to quantitate more immature erythroid cells.[199]

Pure erythroid leukemia is highly associated with *TP53* mutations and complex karyotype and other MDS-related cytogenetic abnormalities.[187] Cases with mutated *TP53* should be classified as AML with mutated *TP53* (**Fig. 46-15**) in the ICC, and cases without such mutations should be carefully assessed for other causes of erythroid hyperplasia. Pure erythroid leukemias must be distinguished from several non-neoplastic disorders that manifest marked dyserythropoiesis. These include megaloblastic anemia caused by vitamin B_{12} or folate deficiency, heavy metal intoxication from arsenic, drug effects, congenital dyserythropoiesis, and exogenous erythropoietin administration. These possibilities should

be considered when the sample lacks *TP53* mutations or MDS-related cytogenetic abnormalities.

Acute Megakaryoblastic Leukemia

Acute megakaryoblastic leukemia is defined by the presence of 20% or more bone marrow blasts, at least 50% of which are megakaryoblasts, in patients who do not meet the criteria for a myeloid neoplasm associated with Down syndrome, AML with t(1;22)(p13.3;q13.1), AML with t(3;3)(q21.3;q26) or inv(3)(q21.3;q6), AML with inv(16)(p13.3q24.3)/*CBFA2T3*::*GLIS2,* and AMLs with *NUP98* translocations or any of the other AML categories otherwise defined, including those with myelodysplasia-related gene mutations and myelodysplasia-related cytogenetic abnormalities.[116,200] With use of these criteria, the acute megakaryoblastic leukemia type of AML, NOS is uncommon. In blood and bone marrow smears, megakaryoblasts are usually medium-to-large-sized cells with a high nuclear-to-cytoplasmic ratio. Nuclear chromatin is dense and homogeneous. Nucleoli are variably prominent. There is scant to moderately abundant cytoplasm, which may be vacuolated. An irregular cytoplasmic border is often noted, and projections resembling budding platelets are occasionally present. Transitional forms between poorly differentiated blasts and recognizable micromegakaryocytes may be observed. In some cases, the majority of the leukemic cells consist of small lymphoid-like blasts. A marrow aspirate may be difficult to obtain because of frequent myelofibrosis. Trephine biopsy sections may reveal morphologic evidence of megakaryocytic differentiation that is not appreciated in the marrow aspirate smears.

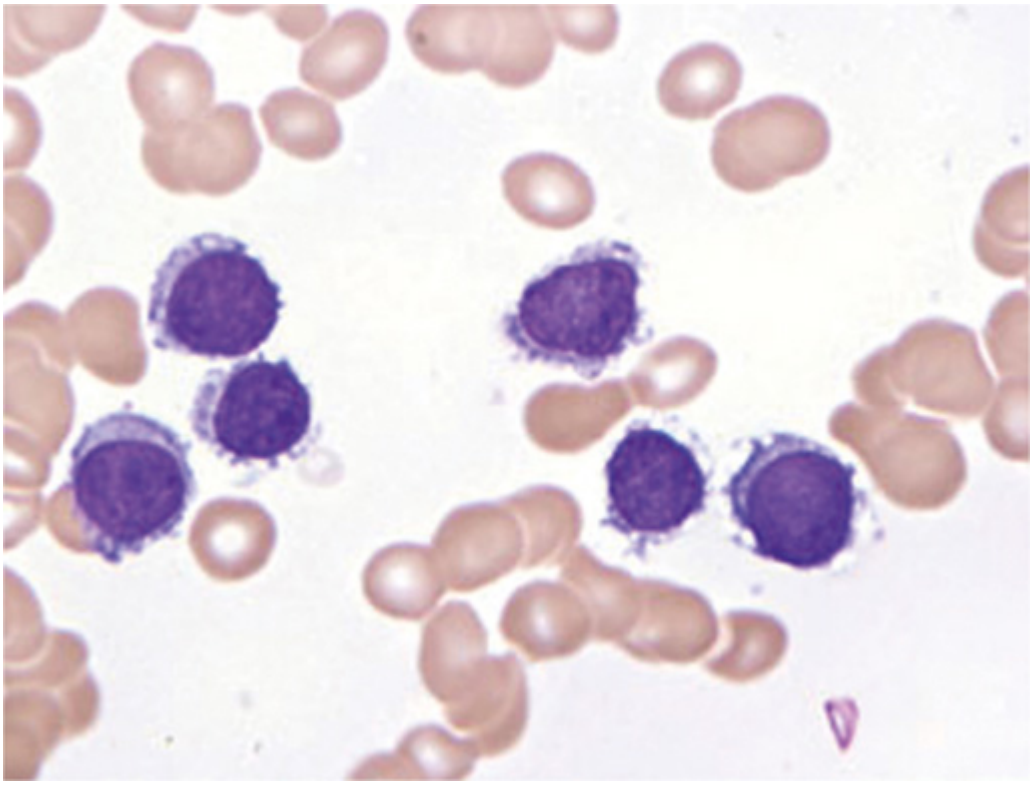

FIGURE 46-15 Acute myeloid leukemia with mutated *TP53,* pure erythroid leukemia type.This rare leukemia exhibits a pure population of erythroblasts with cytoplasmic vacuoles and no myeloblast proliferation. These cells represent more than 80% of peripheral blood and marrow cells and express erythroid-associated markers of hemoglobin and glycophorin. The vast majority of such cases demonstrate mutations of *TP53*.

Identification of a megakaryocyte lineage cannot be made by morphologic features alone and requires immunophenotyping or electron microscopy and ultracytochemistry.[3] The more differentiated blasts are recognized by the presence of demarcation membranes and “bull’s-eye” granules by electron microscopy.

Ultrastructural peroxidase activity is found in the nuclear envelope and endoplasmic reticulum and is absent from the granules and Golgi complexes of leukemic megakaryoblasts. This pattern of localization of the ultrastructural peroxidase reaction distinguishes megakaryoblasts from myeloblasts and is the earliest distinctive, recognizable characteristic of megakaryoblasts. By flow cytometry, the megakaryoblasts are myeloperoxidase negative and may be CD45 negative, CD34 negative, and HLA-DR negative, with variable expression of CD13 or CD33. Aberrant CD7 expression may be seen. Immunophenotyping by flow cytometry or immunohistochemistry with antibodies to megakaryocyte-restricted antigens, such as CD41, CD42b, and CD61, is usually diagnostic. Bone marrow cytogenetics may be difficult to obtain owing to the presence of marrow fibrosis.

Acute Basophilic Leukemia

Acute basophilic leukemia is an extremely rare AML with 20% or more bone marrow blast cells and evidence of basophilic differentiation. Described cases have been defined by morphologic features of basophilic blast cell granules or solely by the ultrastructural detection of basophilic features (**Fig. 46-16**).[201-203] The latter criterion is problematic because electron microscopy studies are not routinely performed on acute leukemias. The blasts may resemble AML without differentiation, lacking myeloperoxidase or Sudan black B. By flow cytometry, they lack CD117 (excluding mast cell leukemia) and show variable expression of CD34 and HLA-DR. CD13 and CD33 are usually detected, and blasts are usually positive for CD123 and CD11b.[204,205] Expression of CD203c in the absence of CD117 is considered fairly specific for a basophilic

lineage.[204] There is no consistent chromosomal abnormality identified in most cases, but a recurring t(X;6)(p11.2;q23.3) *MYB*::*GATA1* appears to occur in male infants with acute basophilic leukemia.[206,207] Other reported cytogenetic abnormalities in acute basophilic leukemia include t(3;6)(q21;p21) and abnormalities involving 12p.[208,209] Other leukemias with basophilia must be excluded, including AML with t(6;9)(p22.3;q34.1), AML with *BCR*::*ABL1,* and blast transformation of CML.

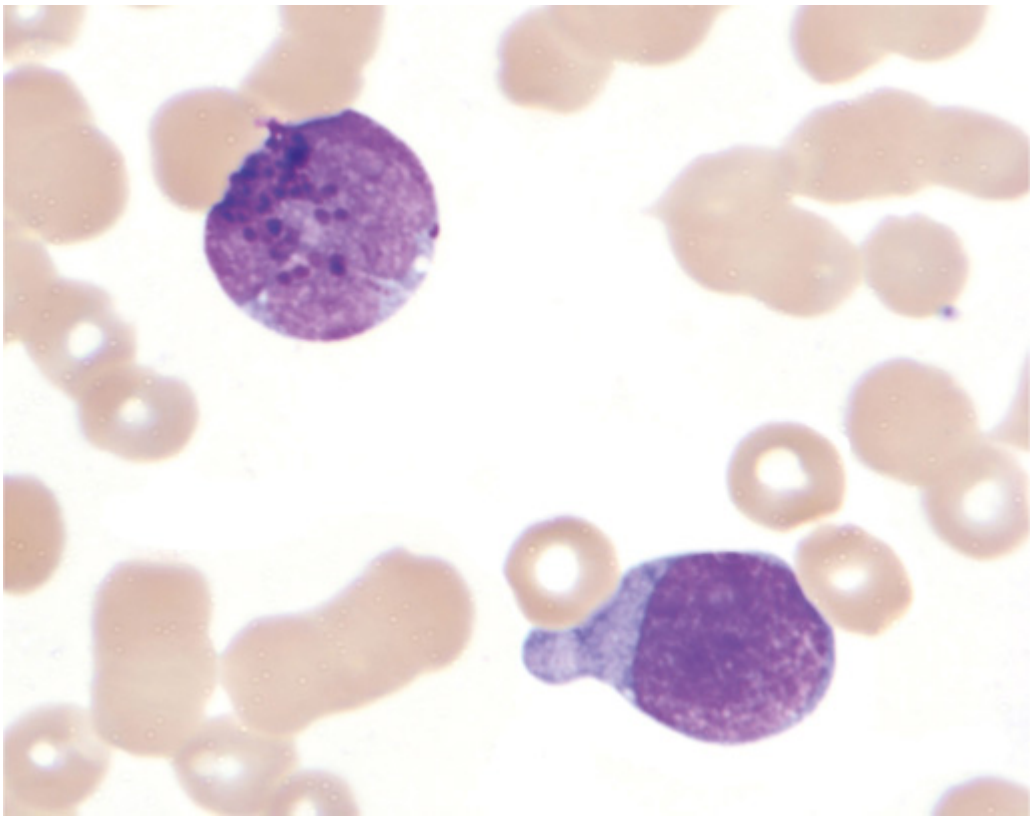

FIGURE 46-16 Acute basophilic leukemia.Blast cell proliferation in which many of the blasts contain basophilic granules. This patient had no history of chronic myeloid leukemia and did not meet the criteria for another type of acute myeloid leukemia and was therefore diagnosed with acute basophilic leukemia.

Acute Panmyelosis With Myelofibrosis

APMF is an extremely rare disorder that is included as a subtype of AML, NOS. It occurs most commonly in adults with pancytopenia and no splenomegaly.[210-212] The marrow is fibrotic and shows panmyelosis, usually involving immature granulocytic,

megakaryocytic, and erythroid cells (**Fig. 46-17**). Marrow myeloblast counts are usually difficult to perform owing to the inability to aspirate marrow as well as the panmyelosis, but most cases have 20% or more marrow blasts. The differential diagnosis of APMF includes primary myelofibrosis and other MPNs in their later stages, acute megakaryoblastic leukemia, AML with myelodysplasia-related gene mutations and myelodysplasia-related cytogenetic abnormalities, MDS with excess of blasts and myelofibrosis, and other neoplasms with fibrosis in the marrow, including metastatic tumors. The lack of splenomegaly helps distinguish this disorder from many of the MPNs. Exclusion of the myelodysplasia-related AML types may be difficult owing to poor aspirates for molecular or cytogenetic analysis, but a diagnosis of either AML with myelodysplasia-related gene mutations or AML with myelodysplasia-related cytogenetic abnormalities takes precedence over APMF. APMF can be distinguished from acute megakaryoblastic leukemia by the frequent expression of CD34 on the blasts of APMF and the proliferation of immature cells from all three lineages, not just megakaryoblasts. APMF has an aggressive course and a more abrupt clinical onset, with fever and bone pain, than MDS with increased blasts and myelofibrosis; however, in some cases, it may be impossible to distinguish APMF from myelodysplasia with fibrosis.[213]

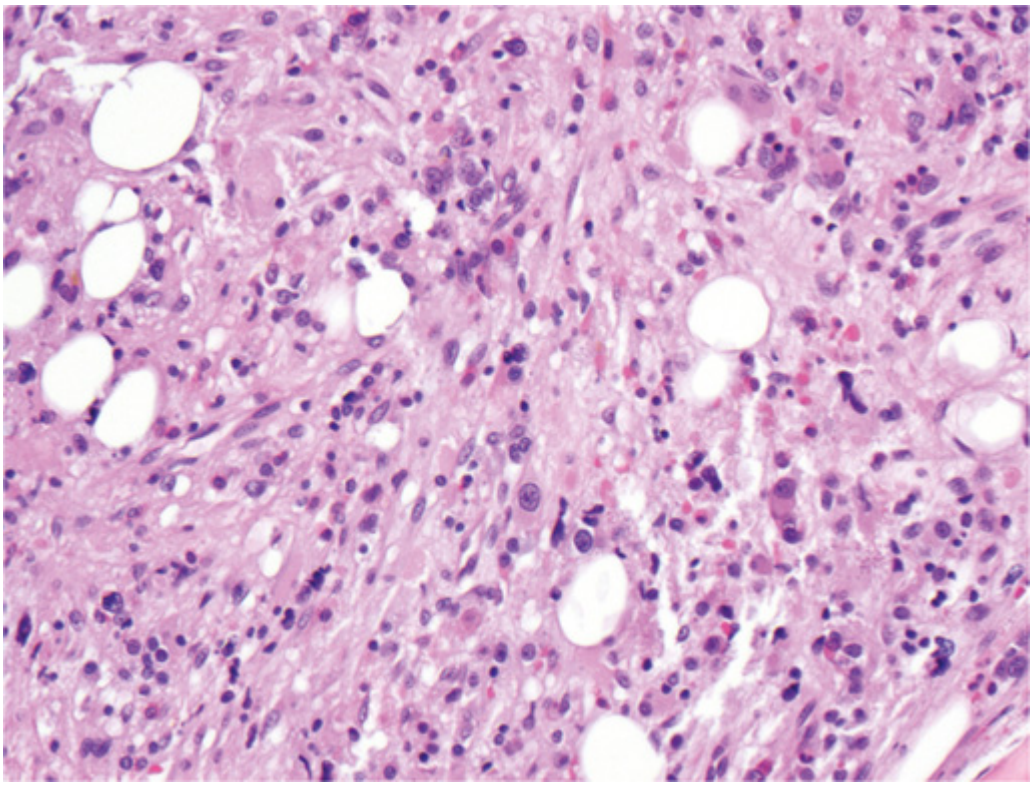

FIGURE 46-17 Acute panmyelosis with myelofibrosis.The marrow is replaced by fibrosis, with admixed immature cells that include myeloblasts, dysplastic and immature megakaryocytes, and erythroid precursors. The patient lacked splenomegaly and other features of a myeloproliferative neoplasm.

MYELOID PROLIFERATIONS OF DOWN SYNDROME

Patients with Down syndrome are at increased risk for both ALL and AML (see also Chapter 45). Infants and children with Down syndrome often have myeloid proliferations in blood and bone marrow that in some cases would meet the criteria for AML.[214]

Because of the unique nature of these myeloid proliferations, they were grouped in a separate category in the 2008 4th ed. WHO classification.[215] Approximately 10% of neonates with Down syndrome manifest a transient myeloproliferative disorder indistinguishable from acute leukemia that is called transient abnormal myelopoiesis (TAM). This proliferation spontaneously resolves in most cases. In the first 4 years of life, children with Down syndrome are at high risk for development of acute megakaryoblastic leukemia. This AML most commonly follows TAM and is phenotypically and, in many respects, genetically identical to the blasts of TAM. After the age of 5 years, the ratio of AML to ALL normalizes to that of the general pediatric population, but children with Down syndrome remain at higher risk for development of acute leukemia. Both TAM and the myeloid leukemia of Down syndrome are associated with mutations in the megakaryocyte transcription factor *GATA1* acquired in utero.[216]

Transient Abnormal Myelopoiesis

TAM presents in the newborn period with a median age at diagnosis of 3 to 7 days.[217,218] Most patients have leukocytosis and increased peripheral blood blasts.[219] The blasts usually show morphologic features similar to megakaryoblasts in other settings, including basophilic cytoplasm with or without coarse basophilic granules and cytoplasmic projections (**Fig. 46-18**). Red blood cell and platelet indices are variable, with near-normal median values. Dysplastic changes of marrow elements may be present. By flow cytometry, the blasts of TAM commonly express moderate CD45 and HLA-DR; the myeloid antigen CD33 with or without CD13; and CD38, CD117, and

CD34.[220-222] They frequently show aberrant CD7 and CD56 expression and evidence of megakaryocytic differentiation, with expression of CD41, CD61, and CD71. Clonal cytogenetic abnormalities are typically limited to trisomy 21, although non-clonal abnormalities are frequently observed. *GATA1* and *JAK3* mutations are both common in TAM.[223-226]

Hepatic dysfunction is a marker for poor outcome in TAM. Patients frequently demonstrate hepatomegaly. Clinically significant liver disease is manifested as hyperbilirubinemia with or without elevated transaminases. Biopsy may demonstrate cholestasis, fibrosis (portal and perisinusoidal), a paucity of bile ducts, variable hepatocellular necrosis, and a variable amount of extramedullary hematopoiesis. Some cases show an abundance of megakaryocyte precursors; others may show only occasional mononuclear cells. This may be a function of their myeloproliferative state and whether the biopsy is performed during TAM, with elevated blast counts, or after the resolution of TAM. Patients with severe perinatal disease may have fibrosis of other organs, including the pancreas and kidneys. Generalized skin involvement by TAM has been reported, including lesions showing perivascular immature cell infiltrates[227] and erythematous maculopapular lesions and indurated subcutaneous nodules.[228]

Only a subset of patients requires intervention because of hyperviscosity, blast counts greater than 100,000/μL, organomegaly with respiratory compromise, renal dysfunction, or disseminated intravascular coagulation. Three risk groups have been described: low risk, with no palpable hepatomegaly or hepatic dysfunction (38% of patients; OS, 92% ± 8%); intermediate risk, with hepatomegaly

and non–life-threatening hepatic dysfunction (40% of patients; OS, 82% ± 11%); and high risk, with a white blood cell count greater than 100,000/μL or life-threatening cardiorespiratory compromise because of TAM (21% of patients; OS, 49% ± 20%). The reported median time to TAM resolution is 46 days. A later myeloid proliferation develops in 10% to 30% of patients, including some treated with low-dose chemotherapy.[217,218]

Myeloid Leukemia Associated With Down Syndrome

An AML-like presentation in Down syndrome typically occurs in the first 3 years of life, often after a prolonged myelodysplasia-like phase.[229] Because cases with 5% to 20% blasts and cases of overt AML are biologically and clinically similar, they are often treated with similar protocols are not separated in MDS and AML types. Acute megakaryoblastic proliferations are the most common. Studies suggest that nearly all myeloid leukemias associated with Down syndrome in children younger than 4 years are megakaryoblastic proliferations.

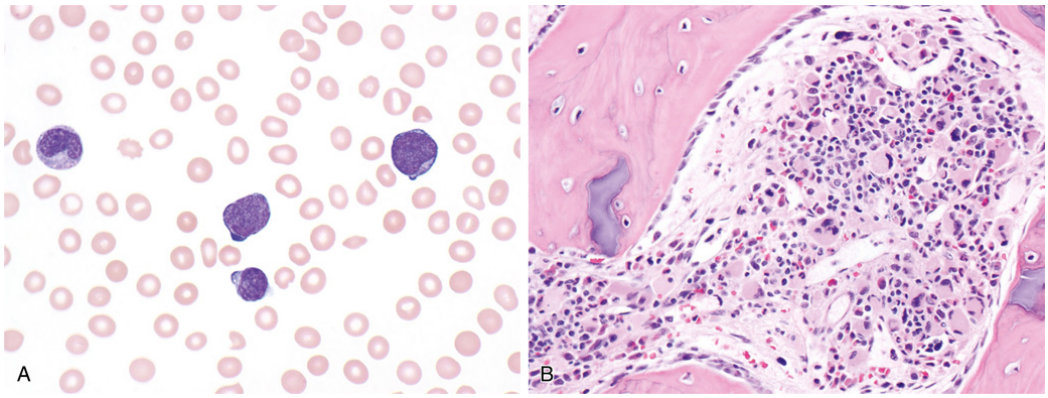

FIGURE 46-18 Transient abnormal myelopoiesis in an infant with Down syndrome.**A,** Peripheral blood from an infant with Down syndrome contains blasts with basophilic cytoplasm and shows cytoplasmic blebbing. These blasts express CD41 and CD61, consistent with megakaryoblasts. **B,** Bone marrow biopsy shows a predominance of immature cells and megakaryocytes.

Blasts in myeloid leukemia associated with Down syndrome can be identified in the blood, bone marrow, liver, and spleen and exhibit features common to megakaryoblasts, as described earlier (**Fig. 46-19**). Dyserythropoiesis is usually evident in the blood (anisopoikilocytosis) and marrow (megaloblastic changes, nuclear contour abnormalities, multinucleate forms). By flow cytometry, the blasts show a similar immunophenotypic profile to that of TAM, with a few possible differences.[220,222,223] The blasts of AML may show more consistent expression of CD13 and CD11b, with less CD34 (93% of TAM cases compared with 50% of myeloid leukemia associated with Down syndrome) and possibly less HLA-DR. In addition, myeloid leukemia associated with Down syndrome often

demonstrates more severe cytopenias, more background dysplasia and marrow fibrosis, and more frequent clonal karyotypic abnormalities other than trisomy 21 (including complete or partial trisomies of chromosomes 1 and 8) compared with TAM.[222] Despite these clonal abnormalities, many of which are considered myelodysplasia related in non–Down syndrome patients, the prognosis of myeloid leukemia associated with Down syndrome is very good compared with that in non–Down syndrome patients, especially when it is treated with HiDAC. However, the prognosis in patients older than 5 years is similar to that in non–Down syndrome patients.[230] Age is a significant predictor of outcome even in younger children. The event-free survival for children aged 0 to 2 years is 86%; for those aged 2 to 4 years, it is 70%; and for those older than 4 years, it is 28%.[230] There is a trend toward more frequent monosomy 7 in older children, but it is not clear whether this significantly affects outcome. Although *GATA1* mutations are present in both TAM and myeloid leukemia associated with Down syndrome, myeloid leukemias in this setting appear to arise from a *GATA1*-mutated TAM clone that has acquired additional mutations. Implicated additional mutations include *CTCF, EZH2, KANSL1, JAK2, JAK3, MPL, SH2B3,* and RAS pathway genes.[231,232]

MYELOID SARCOMA

Myeloid sarcoma is an extramedullary mass forming proliferation of myeloid blasts that may be associated with a concurrent myeloid neoplasm involving the bone marrow, but such an association is not required.[233-237] In some cases, myeloid sarcoma may herald relapse in a patient with previously treated disease. In others, it may be the

first indication of acute leukemia. In adults, roughly one-third of myeloid sarcomas present with concurrent myeloid disease (including AML, MDS, MPN, and MDS/MPN), and one-third have a history of a prior myeloid neoplasm. By definition, the infiltrates efface the underlying tissue architecture. Synonyms include chloroma, granulocytic sarcoma, and extramedullary myeloid tumor. The de novo presence of myeloid sarcoma is diagnostic of AML, regardless of the bone marrow or blood status. The most common site of involvement is the skin, followed by mucous membranes, orbits, central nervous system, lymph nodes, bones, gonads, and other internal organs. Myeloid sarcoma is considered more common in pediatric AML, occurring in approximately 10% of cases,[198] although the true incidence in adults is unknown. The frequency in children may reflect associations with the t(8;21), inv(16), and 11q23.3 translocation subtypes, which are relatively more common in younger patients.

Previously, three subtypes of myeloid sarcoma were described on the basis of the degree of maturation: blastic, immature, and differentiated.[199,237] Such subtyping is no longer considered relevant, but it may be useful in recognizing the morphologic variability of the myeloid blast infiltrate. Myeloid sarcoma should not be considered a type of AML but rather a type of presentation of AML or blast transformation. Every attempt should be made to classify myeloid sarcoma cytogenetically and immunophenotypically, in the same manner as if it were AML in the bone marrow. In patients with concurrent bone marrow or peripheral blood involvement, this classification is straightforward. In patients with de novo disease limited to myeloid sarcoma, precise classification

may be difficult. Repeated biopsy or fine-needle aspiration may be necessary to obtain smears and fresh material for flow cytometric immunophenotyping and cytogenetic and molecular genetic studies to properly classify the AML.[238]

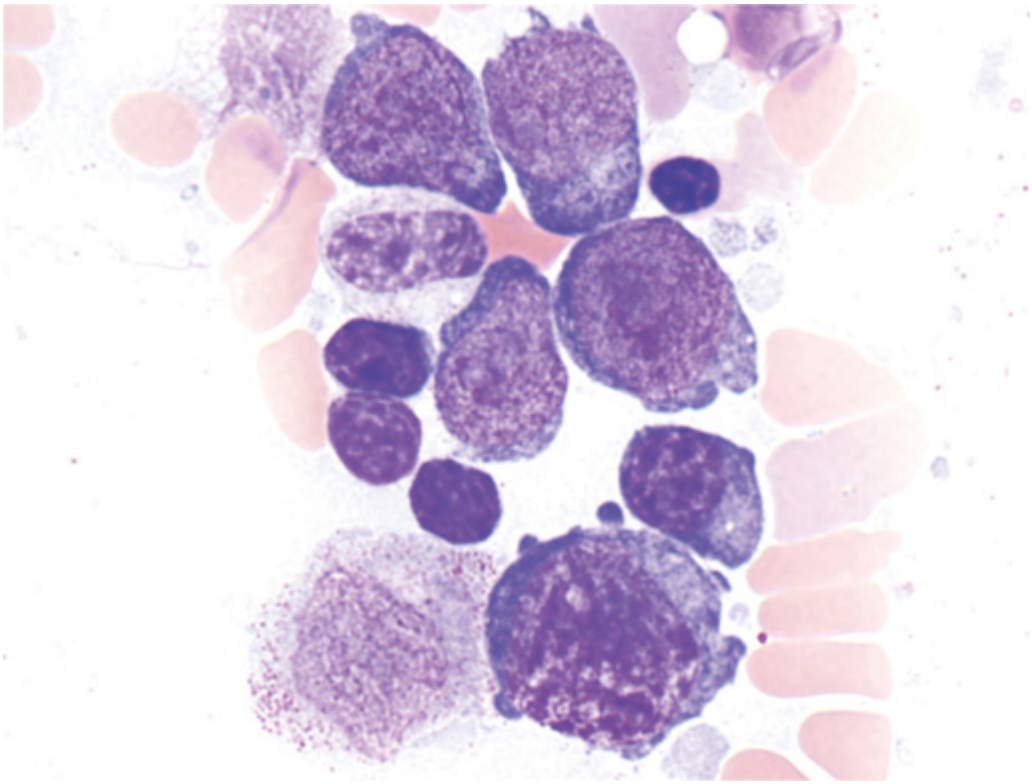

FIGURE 46-19 Myeloid neoplasm associated with Down syndrome.Bone marrow shows abnormal erythroid precursors and blasts that mark as megakaryoblasts. Although the features are similar to those in Figure 46-18, the diagnosis of myeloid neoplasm associated with Down syndrome rather than transient abnormal myelopoiesis is dependent on the child's age and the clinical features.

The myeloblasts of myeloid sarcoma usually form sheets of mononuclear cells, with an interfollicular pattern common in lymph nodes (**Fig. 46-20**). The blast cells may have admixed maturing granulocytes, erythroid precursors, or megakaryocytes, which are useful clues to the myeloid lineage of the immature cell population (**Fig. 46-20A**). Eosinophilic myelocytes are the most easily recognized maturing cell population. Although they are present in only a subset of myeloid sarcomas, their presence is highly associated with a myeloblast cell population. The blasts themselves may have round to folded nuclei, usually with fine nuclear chromatin with a more stippled pattern than that typically seen in large B-cell lymphoma. Flow cytometric immunophenotyping usually demonstrates a lack of lineage-specific B-cell or T-cell markers and expression of myeloid or myelomonocytic markers, such as CD13, CD33, myeloperoxidase, CD14, or CD64. However, as with AML in other sites, aberrant lymphoid antigen expression commonly occurs, and a relatively large panel of antibodies is useful to ensure accurate lineage determination. Fewer antibodies are available for characterization in paraffin sections, but lack of specific B-lineage or T-lineage markers with expression of myeloperoxidase, CD33, or the monocyte-specific marker CD163 is fairly specific for myeloid sarcoma. Other markers that are commonly positive but less lineage-specific are CD43, lysozyme, and CD68. Only about half of cases are CD34 positive, but CD117 expression is apparently more common.[239]

Myeloid sarcoma shows some variability in presentation. Nearly one-quarter of children with AML with t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1* develop myeloid sarcoma.[240,241] Head and neck localization with orbital, skull, and central nervous

system extramedullary involvement is most common in this group. A smaller percentage (approximately 10%) of adults with t(8;21) AML have myeloid sarcoma,[240] without the pattern of head and neck localization. Skin involvement in pediatric patients (leukemia cutis) tends to occur at a younger age (median, 2.6 years), and the skin lesions are most commonly associated with 11q23.3 translocations and with abnormalities of chromosome 16. Myelomonocytic morphology is most common in this setting. A unique and rare subset of skin tumors appears to represent a congenital leukemia, with multiple skin lesions of myeloid sarcoma presenting within the first week after birth (a form of "blueberry muffin" baby). In some of these babies, disease is limited to the skin. Such cases tend to have spontaneous remissions, sometimes during a period of days. The most common AML type in this setting is AML with t(8;16) (p11.2;q13.3)/*KAT6A*::*CREBBP*,[127] which is frequently associated with erythrophagocytosis, therapy-related disease, and poor prognosis in adults. Because chemotherapy is very toxic to newborns, some reports recommend careful observation for patients with congenital myeloid sarcoma limited to the skin and no systemic manifestations, cytopenias, or lymph node involvement. Some spontaneously remitting cases with t(8;16) recur. Reserving chemotherapy for recurrences in spontaneously remitting cases may be an appropriate course of action,[242] sparing the infant excessive and possibly unnecessary toxicity. In contrast to babies with t(8;16) disease, those with 11q23.3 translocations tend to have a poor prognosis.

The clinical significance of myeloid sarcoma remains unclear, but the site of involvement may affect outcome, with improved survival

reported for isolated cases involving the pelvis and genitourinary organs, eyes, gonads, and gastrointestinal mucosa.[243] Other than the self-limited congenital forms, it is not clear whether myeloid sarcoma confers any specific prognosis in the era of HiDAC therapy, particularly when cases are classified according to known risk groups.[240,244] Low-dose radiation therapy may be useful for the emergent treatment of life-threatening or organ-threatening (e.g., orbital) myeloid sarcomas. The use of radiation therapy in the routine management of these patients does not appear to be indicated, however. Hematopoietic cell transplantation may be appropriate, especially if myeloid sarcoma presents early in the patient's disease course.[238,245,246]

The differential diagnosis of myeloid sarcoma versus lymphoma, especially diffuse large B-cell lymphoma, lymphoblastic lymphoma, blastic mantle cell lymphoma, and Burkitt lymphoma, is challenging on morphologic grounds alone. Fine nuclear chromatin with a high mitotic rate is often helpful in differentiating large B-cell lymphoma, which usually shows more distinct nucleoli and chromatin clearing. The presence of admixed erythroid cells, megakaryocytes, or eosinophilic myelocytes is a helpful clue to the possibility of a myeloid tumor. Immunophenotyping, however, is essential to the proper diagnosis of myeloid sarcoma. Cases of suspected lymphoma that lack B-lineage or T-lineage–specific markers, including those with a CD43-only immunophenotype, should be further evaluated for evidence of myeloid sarcoma. Aberrant B-lineage marker expression, particularly CD19 and PAX5, in AML with t(8;21)(q22;q22.1) can lead to an incorrect diagnosis of B-cell lymphoma in a case of myeloid sarcoma. Subsets of APL and AML with inv(16)

(p13.1q22) or t(16;16)(p13.1;q22)/*CBFB*::*MYH11* aberrantly express the T-lineage–associated marker CD2 and can be mistaken for T-cell lymphomas. CD7 and CD56 are also frequently expressed in myeloid sarcoma, and neither marker should be used alone to diagnose a T-cell or natural killer cell malignant neoplasm. Rare extramedullary tumors of AML (megakaryocytic) with t(1;22)(p13.3;q13.1)/*RBM15*::*MRTFA* often show cell clustering in infants and may be mistaken for small, blue, round cell tumors of infancy. Paraffin detection of CD41, CD42b, and CD61 expression is useful in these cases, which are characteristically myeloperoxidase negative. Von Willebrand factor and LAT (linker for activation of T cells) are less-specific markers of megakaryocytic lineage. Without knowledge of this tumor and investigation with megakaryocytic markers, the diagnosis may be missed.

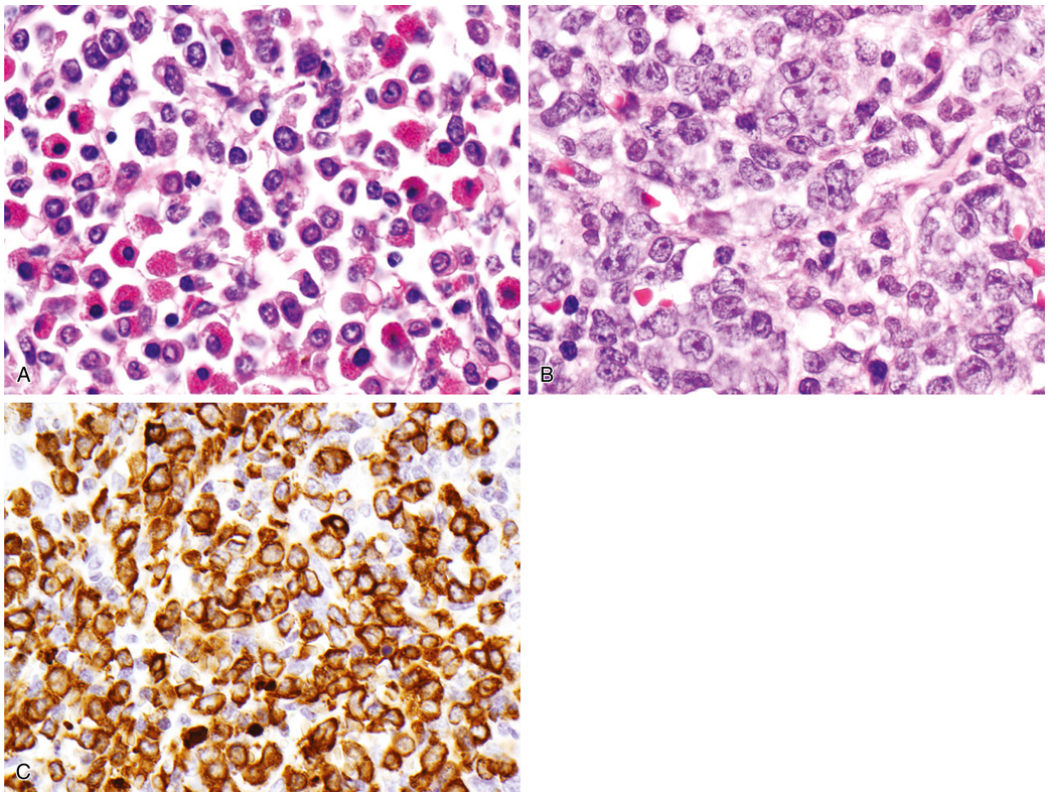

FIGURE 46-20 Myeloid sarcoma.**A,** Admixed eosinophil precursors in this myeloid sarcoma are a clue that the mononuclear cells may be myeloid cells. **B,** This more undifferentiated proliferation mimics a diffuse large B-cell lymphoma, with prominent nucleoli and some chromatin clearing. The myeloid blasts have finer nuclear chromatin than most large B-cell lymphomas, however, and the cells are myeloperoxidase positive **(C)** by immunohistochemistry.

Other aspects of the differential diagnosis include the interpretation of sparse immature myeloid cell infiltrates in extramedullary sites. The diagnosis of myeloid sarcoma should be restricted to tumors that form space-occupying lesions. Patients with

AML may have leukemic infiltrates in multiple sites that do not form masses that disrupt normal tissue architecture, and such cases should not be considered myeloid sarcoma. Patients receiving growth factors may have left-shifted granulocytes in various tissues that do not form masses, and these should not be overinterpreted as myeloid sarcoma. Similarly, maturing granulocyte proliferations of the skin must be distinguished from a dermal myeloid sarcoma. Sweet syndrome,[247] also known as acute febrile neutrophilic dermatosis, may occur in patients with AML, but this does not represent an extramedullary leukemic infiltrate. Sweet syndrome is associated with pronounced dermal edema with a marked mature neutrophilic infiltrate, in contrast to the more immature cell infiltrate of cutaneous myeloid sarcoma. Sweet syndrome often resolves with treatment of the associated AML; the lesions also respond to systemic corticosteroid therapy.

DIAGNOSTIC QUALIFIERS IN ACUTE MYELOID LEUKEMIA

The ICC introduced the use of diagnostic qualifiers that slightly alter the approach to the diagnosis or MDS, AML, and MDS/AML.[12] Diagnostic qualifiers in AML relate to (1) therapy-related disease; (2) progression from MDS or MDS/MPN; and (3) presence of a germline predisposition. In prior classifications, therapy-related myeloid neoplasms were grouped together and not further classified. Though it was understood that some types of prior therapy correlate with genetic abnormalities, such as MDS-related cytogenetic abnormalities or *KMT2A* translocations (see Figs. **46-21** and **46-22**), these findings were not used diagnostically. Though a history of

prior cytotoxic therapy is a poor prognostic indicator in these disorders, the underlying genetic abnormalities remain prognostically significant. For this reason, such cases should now be diagnosed similar to de novo cases with the qualifier “therapy-related” added after the diagnosis. Cases arising from prior MDS or MDS/MPN should also be diagnosed like de novo disease with a comment that they represent progression of the underlying disorder (i.e., AML with mutated *TP53* progressing from MDS). Finally, many germline gene abnormalities are now recognized (see Chapter 45) that predispose to the development of MDS, AML, and even ALL. Detection of these germline mutations is not sufficient for a diagnosis of AML, MDS, or MDS/AML, but when the clinical features meet criteria for those disorders, the germline abnormality should be noted to clarify the familial risk associated with the neoplasm. The proposed WHO 5th ed. classification appears to take a different approach to these disorders. They retain the category of myeloid neoplasms postcytotoxic therapy but suggest that a recurring genetic abnormality be described in the pathology report. Cases with prior MDS or MDS/MPN that evolve to AML appear to fall into the proposed WHO category of AML, myelodysplasia-related. It is unclear at the time this chapter was prepared how the proposed WHO 5th ed. classification will address germline abnormalities in the setting of AML.

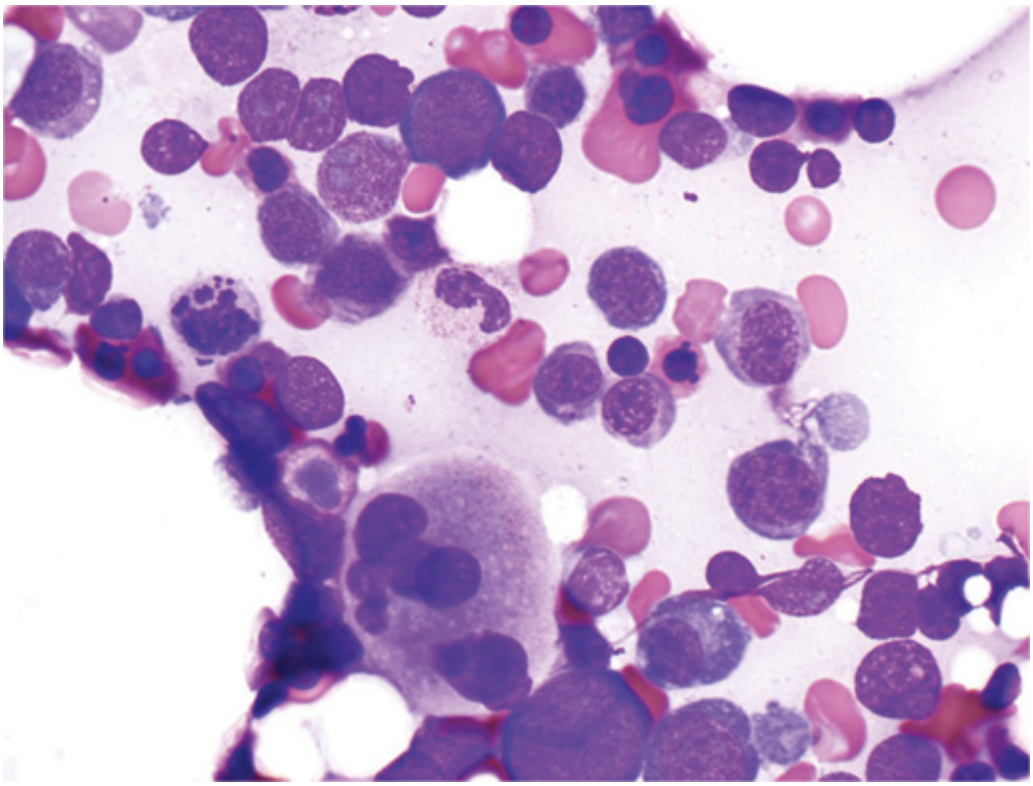

FIGURE 46-21 Acute myeloid leukemia (AML) with myelodysplasia-related cytogenetic abnormalities (complex karyotype), therapy-related after alkylating agent chemotherapy.Multilineage dysplasia is characteristically present. Such cases are now diagnosed similar to other AML types with “therapy-related” added as a qualifier.

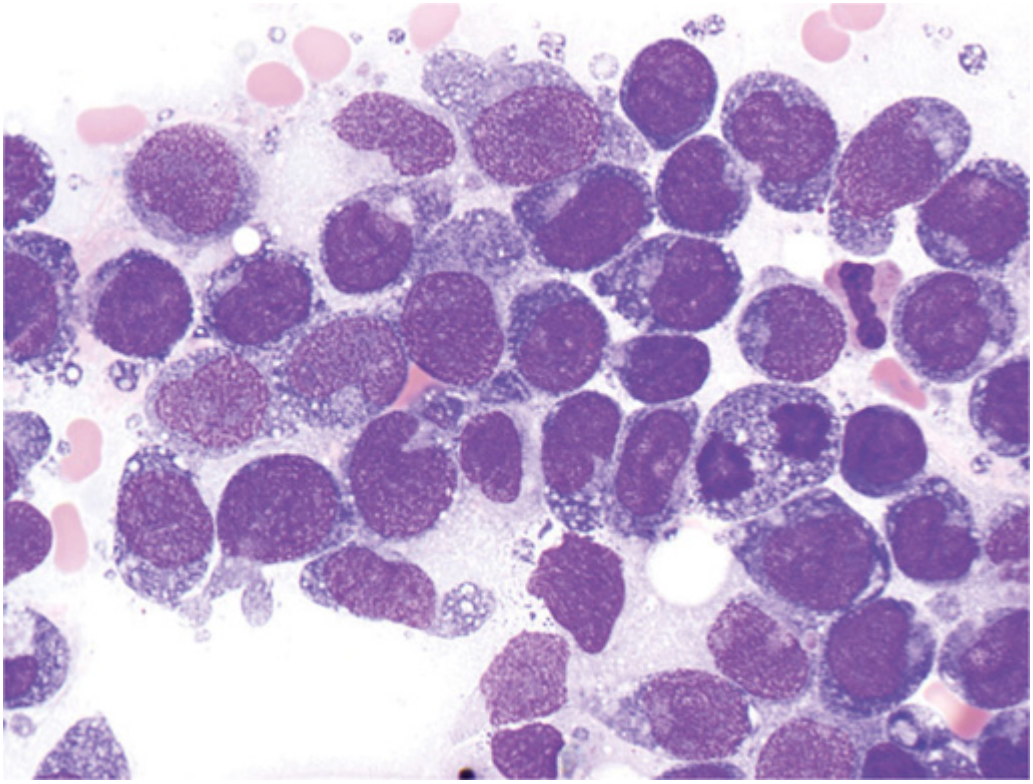

FIGURE 46-22 Acute myeloid leukemia (AML) with t(9;11)(p21.3;q23.3)/*MLLT3*::*KMT2A*, therapy-related after topoisomerase II inhibitor therapy.This case shows blasts with monocytic features and no background dysplasia, typical of therapy-related disease with this cytogenetic abnormality.

INTEGRATED APPROACH TO THE DIAGNOSIS OF ACUTE MYELOID LEUKEMIA

A complex approach is necessary to diagnose and appropriately classify cases of AML.[248] This requires an integration of morphologic, immunophenotypic, cytogenetic, and molecular

genetic data. Such integration is best done in a single, final pathology report. Such reports need to be amended as genetic results become available, and diagnoses will be revised on the basis of those data. Although morphologic and immunophenotypic clues can suggest specific cytogenetic abnormalities, cytogenetic or molecular genetic confirmation is essential. Diagnosis based on any single element of the workup of AML is fraught with difficulty and pitfalls. Some cases with 10% or more peripheral blood or bone marrow blast cells on morphologic examination are now considered acute leukemia if they have specific recurring cytogenetic abnormalities. These cases might be missed if the appropriate cytogenetic studies are not available to the diagnosing pathologist. Similarly, samples with high numbers of marrow red blood cell precursors may result in falsely elevated blast cell counts when such counts are performed only by flow cytometry, and these cases may be overdiagnosed as AML. Cases of AML with specific recurring cytogenetic abnormalities, such as AML with t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1,* may be misdiagnosed as mixed phenotype acute leukemia if only flow cytometry methods are used for diagnosis.

Although the various studies necessary to diagnose AML may be performed in different laboratories, the pathologist must review all the diagnostic data and incorporate them into a final report that explains how the different studies contribute to the diagnosis. **Figure 46-23** shows a diagnostic algorithm for the integrated approach to these specimens. This approach adds an extra layer of complexity to pathology reporting, but it also provides the most clinically relevant diagnosis for a given case. Based on that diagnosis, appropriate treatment can be administered, and markers for the

detection of residual disease can be identified, resulting in better patient care.

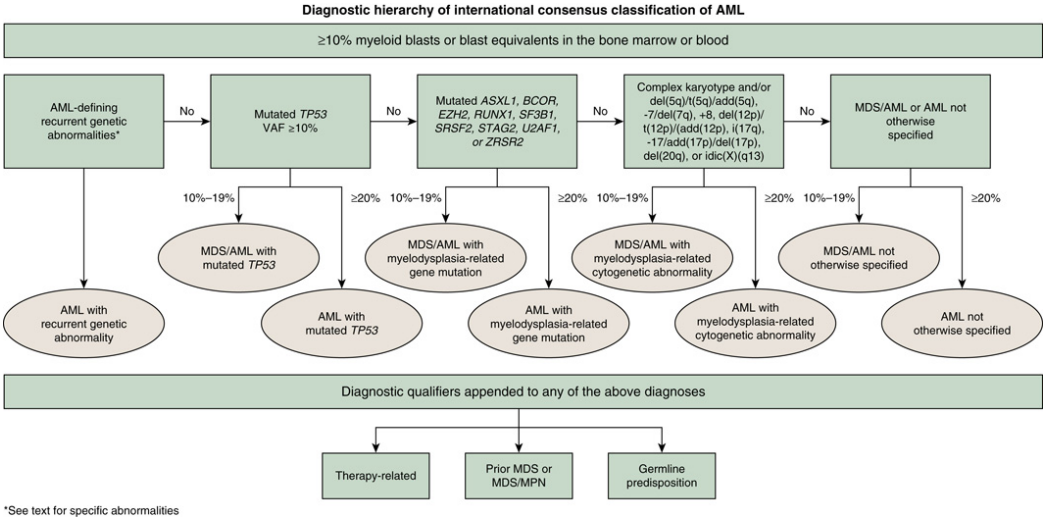

FIGURE 46-23 Diagnostic hierarchy of acute myeloid leukemia (AML) using the International Consensus Classification (ICC).*AML,* Acute myeloid leukemia; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *VAF,* variant allele frequency. Adapted from Dohner H, Wei AH, Appelbaum FR, et al. Diagnosis and management of AML in adults: 2022 recommendations from an international expert panel on behalf of the ELN. Blood. 2022;140(12):1345-1377.

Pearls and Pitfalls

- Manual blast cell counts on aspirate smears are still required for classification and take precedence over flow cytometry or other methods of blast cell enumeration.
- Immunohistochemical enumeration of blast cells is useful particularly in the presence of marrow fibrosis or marked hypocellularity (fatty marrows).
- Both flow cytometry and immunohistochemistry may underestimate marrow blast counts because of a variety of factors, including lack of CD34 expression on all blasts.
- Acute myeloid leukemia (AML) with monocytic features may mimic chronic myelomonocytic leukemia in the peripheral blood, so bone marrow examination is required for diagnosis.
- Close communication with the cytogenetics laboratory is essential to alert staff to potentially subtle abnormalities such as inv(16)(p13.1q22).
- Folded blast cell nuclei without other features of monocytic differentiation should raise concern for hypogranular acute promyelocytic leukemia (APL).
- Hypogranular APL often has weak CD34 expression.
- Admixed eosinophilic myelocytes, erythroid precursors, or megakaryocytes in an extramedullary mononuclear cell proliferation should raise concern for myeloid sarcoma.
- A final diagnosis of AML or myelodysplastic syndrome (MDS)/AML cannot usually be made until results of immunophenotyping and genetic studies are complete, requiring amended reports.

- Gene-mutation panels add prognostic significance to an AML or MDS/AML diagnosis even when they do not alter the diagnosis.

CONCLUSION

Introduction

The myeloproliferative neoplasms (MPNs) are clonal hematopoietic disorders characterized by proliferation of cells of one or more of the myeloid lineages: erythroid, granulocytic, or megakaryocytic. Initially, the proliferation in the bone marrow is effective and associated with maturation of the neoplastic cells that leads to increased numbers of mature granulocytes, red blood cells (RBCs), and platelets in the peripheral blood. Splenomegaly and hepatomegaly are common and caused by the sequestration of excess blood cells, extramedullary hematopoiesis (EMH), or both in these organs. Despite an insidious onset, each MPN entity has the potential to progress to bone marrow failure because of myelofibrosis, ineffective hematopoiesis, transformation to a blast phase (BP), or any combination of these events. Disease progression is usually accompanied by genetic evolution. Entities included in both the International Consensus Classification 2022 (ICC) and proposed World Health Organization classification (proposed WHO 5th edition) of MPNs are listed in **Box 47-1** and include chronic myeloid leukemia (CML); chronic neutrophilic leukemia (CNL); essential thrombocythemia (ET); primary myelofibrosis (PMF, including both prefibrotic and overtly fibrotic variants/stages); polycythemia vera (PV); chronic eosinophilic leukemia, not otherwise specified (CEL, NOS); and MPN, unclassifiable (MPN-

U).[1,2] Among these clinicopathologic entities, ET, PV, and PMF share similar genetic and bone marrow morphologic characteristics, especially in regard to their close association with *JAK2/CALR/MPL* mutations, with *JAK2* mutation being the most prevalent in each of these entities. This chapter provides an integrated diagnostic approach to MPNs including hematologic, morphologic, cytogenetic, and molecular genetic findings.

Box 47-1 Classification of Myeloproliferative Neoplasms

- Chronic myeloid leukemia
- Chronic neutrophilic leukemia
- Essential thrombocythemia
- Primary myelofibrosis
  - Early/prefibrotic primary myelofibrosis
  - Overt primary myelofibrosis
- Polycythemia vera
- Chronic eosinophilic leukemia, not otherwise specified*
- Myeloproliferative neoplasm, unclassifiable

* Discussed in **Chapter 50**.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Etiology and Pathogenesis

The cause of MPNs is not known in most cases. There are reports of CML, PV, and PMF after exposure to ionizing irradiation, but except for cases of CML after the atomic bomb explosions in Hiroshima and Nagasaki, documented instances are rare.[3-6] Most cases of MPN are sporadic, but an inherited susceptibility has been described. Relatives of patients with MPNs have an increased risk for development of PV, ET, or PMF, and many families have been reported with multiple members affected.[7-11] In some, the inheritance pattern is autosomal dominant with incomplete penetrance; in other families, the mode of inheritance is not clear. Single-nucleotide polymorphisms of specific genes in the germline reportedly predispose to acquisition of somatic mutations important in the pathogenesis of MPNs. The best-known predisposing factor for sporadic MPNs associated with the acquired somatic *JAK2* V617F mutation is the germline *JAK2* 46/1 haplotype, which may figure in the familial predisposition for PV, ET, and PMF. However, this haplotype is relatively common, and most individuals who carry it do not develop an MPN.[12] Rare cases of CNL with familial/germline predisposition have been reported.[13,14]

Although a complete understanding of the cellular defects in MPNs is still evolving, there is considerable information about specific genetic abnormalities that contribute to their pathogenesis. A major breakthrough in unraveling the pathogenesis of MPNs occurred in 1960, when Nowell and Hungerford described the chromosomal abnormality in CML, the Philadelphia (Ph) chromosome[15] (**Fig. 47-1**). Rowley demonstrated that the Ph

chromosome results from the reciprocal translocation of genetic material between chromosomes 9 and 22, that is, t(9;22)(q34.1;q11.2).[16] This translocation was subsequently shown to fuse sequences of the *BCR* gene on chromosome 22 and of the *ABL1* gene on chromosome 9, resulting in an abnormal fusion gene, *BCR*::*ABL1*, that encodes a chimeric BCR::ABL1 protein with a constitutively activated tyrosine kinase (TK) derived from the translocated *ABL1*[17-20] (Figs. **47-2** and **47-3**). Experimental evidence has shown the BCR::ABL1 protein is necessary and sufficient for the initiation of CML.[21,22] The constitutively activated TK leads to autophosphorylation of BCR::ABL1, which in turn autophosphorylates other sites on the protein to activate a network of downstream signaling pathways including JAK/STAT, PI3K/AKT, RAS/MEK, mTOR, Src kinase, and BCL2/BCL-XL, among others (**Fig. 47-4**), that results in growth factor independence, inhibition of cell death and autophagy, and defects in cellular adhesion.[23-25] In essence, BCR::ABL1 gains control of major cellular pathways to promote the leukemic state. An understanding of the molecular events related to the abnormal signaling pathways in CML led to the design and synthesis of small molecules that target and inhibit the TK activity of BCR::ABL1. Imatinib was the first such TK inhibitor (TKI) to be used clinically. It competes with adenosine triphosphate for binding to the BCR::ABL1 kinase domain and prevents phosphorylation of tyrosine residues on BCR::ABL1 substrates. Its ability to induce remission in most patients provided further proof of the central role of BCR::ABL1 in the pathogenesis of CML.[26] However, evidence suggests that the CML leukemic stem cell, which

is largely quiescent, may not rely on BCR::ABL1 kinase activity for survival.[27,28]

FIGURE 47-1 Karyotype showing the Philadelphia chromosome, der(22q), which results from the translocation of material between 9q34 and 22q11.2 *(arrows)*. Courtesy Dr. Yanming Zhang, University of Chicago.

Mutations of the Janus 2 kinase gene, *JAK2* V617F and *JAK2* exon 12,[29-32] the myeloproliferative leukemia virus oncogene *MPL,*[33] and the calreticulin gene *(CALR)*[34,35] represent driver mutations in the *BCR*::*ABL1*-negative MPNs PV, ET, and PMF. Mutations in these genes affect encoding proteins that directly or indirectly activate downstream signaling in the JAK-STAT pathway and lead to myeloproliferation. In addition, activating mutations of the colony-

stimulating factor 3 receptor gene *(CSF3R)* have been recognized in chronic neutrophilic leukemia (CNL)[36] (**Table 47-1**).

The JAK kinases are essential to cytokine signaling and signal transduction through their association with homodimeric type 1 cytokine receptors that lack intrinsic kinase activity. The JAK2 protein is the sole JAK kinase that associates with the erythropoietin (EPO) receptor, EPOR. It also associates with the thrombopoietin (TPO) receptor, MPL, and G-CSFR, the granulocyte colony-stimulating factor (G-CSF) receptor, among others.[37,38] Normally, engagement of the cytokine receptor with its ligand results in receptor dimerization, followed by autophosphorylation and transphosphorylation of the receptor and of JAK2 kinase. The activated JAK2-receptor complex then leads to recruitment and phosphorylation of substrate molecules, including signal transducers and activators of transcription (STAT) proteins, which subsequently leads to target gene transcription in the nucleus.[29-31] The *JAK2* V617F mutation is an acquired somatic mutation found in all myeloid lineages and in some B and T lymphocytes in affected individuals.[39] The V617F mutation occurs in exon 14 of the gene and affects a domain (JH2) that lacks kinase activity but serves instead as a negative regulator of the active JAK2 kinase domain. The V617F mutation leads to loss of function of the inhibitory JH2 domain, resulting in a gain of function of JAK2 TK activity, that is, JAK2 is constitutively activated and continually induces JAK-STAT signaling.[40] The *JAK2* exon 12 mutation reportedly has a similar function.[41] *JAK2* V617F is found in about 96% of cases of PV, 55% to 60% of cases of PMF, and 50% to 60% of cases of ET, in which it can

be considered a driver mutation. Mutated *JAK2* exon 12 is found in 3% of patients with PV but rarely in PMF or ET.[42,43]

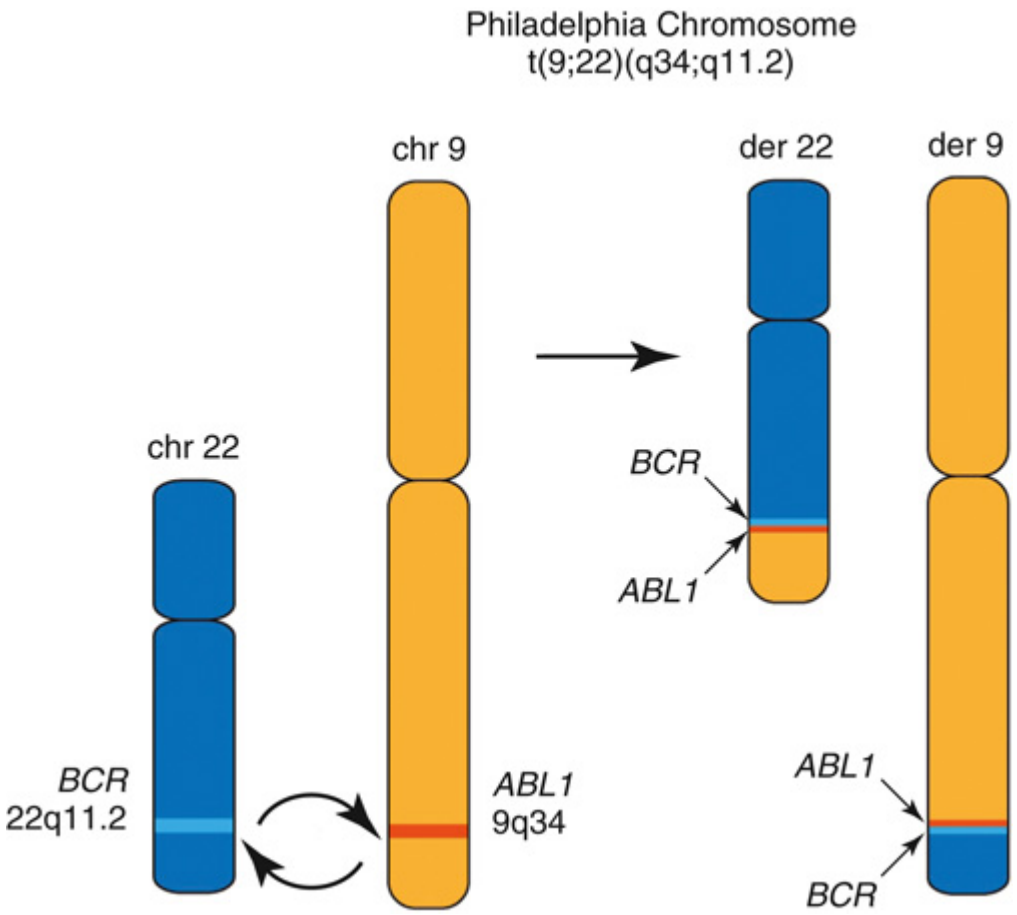

FIGURE 47-2 The Philadelphia chromosome, der(22q), results from the reciprocal translocation of a portion of the *ABL1* gene on chromosome 9 at band q34 to the region of the *BCR* gene on chromosome 22 at band q11.2. In turn, a portion of *BCR* is translocated to chromosome 9 to the region of *ABL1*. In 5% to 10% of patients with chronic myeloid leukemia, cryptic or complex rearrangements result in a *BCR*::*ABL1* fusion gene, even though no Philadelphia chromosome is detected cytogenetically.

Megakaryocyte proliferation and maturation are regulated by TPO, which binds to the cytokine receptor MPL to induce signaling through the JAK-STAT pathway. Gain of function mutations of exon 10 of *MPL,* the gene encoding MPL, lead to cytokine-independent growth through activation of JAK-STAT. Mutations of *MPL,* the most frequent of which is *MPL* W515L/K, are present in about 3% of cases of ET and 7% to 10% of cases of PMF but rarely, if at all, in PV.[44,45]

Somatic mutations are found in exon 9 of *CALR,* the gene that encodes calreticulin, a multifunction calcium-binding protein chaperone mostly localized in the endoplasmic reticulum.[34,35] The mutations are base pair insertions or deletions, all of which lead to a frameshift to the same alternative reading frame and a novel C-terminal peptide in the mutant protein. Two major variants represent more than 80% of the *CALR* mutations. The type 1 variant is a 52-base pair deletion, whereas the type 2 variant is a 5-base pair insertion. The mutant protein is thought to enhance JAK-STAT signaling. Approximately 20% to 25% of patients with ET have mutated *CALR,* and a similar incidence is seen in PMF; the mutation is not seen in PV. Evidence suggests that the type of *CALR* mutation may influence the clinical findings in MPNs that carry mutated *CALR;* type 2 mutations, as opposed to type 1, are associated with higher platelet counts in ET and shorter survival times in PMF.[46,47]

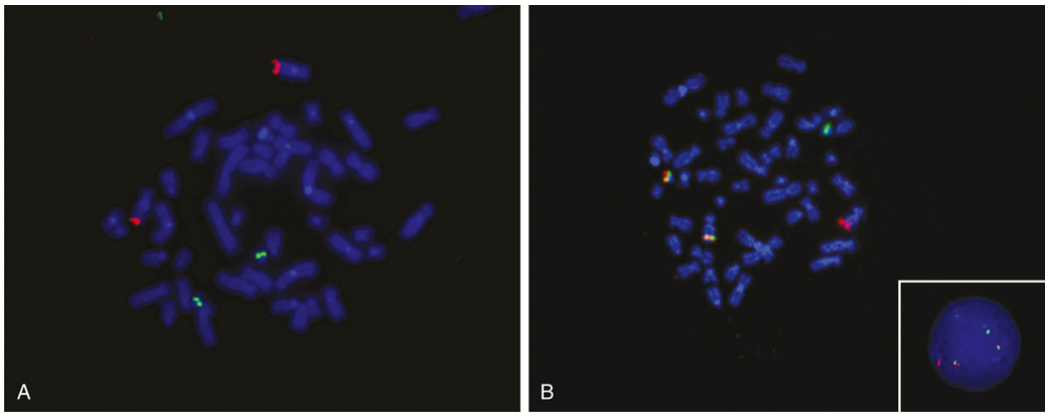

FIGURE 47-3 Fluorescence in situ hybridization for t(9;22)(q34;q11.2) with dual color and dual fusion probes on a normal metaphase cell **(A)** and a metaphase cell from a patient with chronic myeloid leukemia **(B)**, including an interphase cell *(inset)*. The *ABL1* and *BCR* probes are labeled with SpectrumOrange and SpectrumGreen (Vysis Corporation, Downers Grove, Il.), respectively. In normal cells **(A)**, two orange signals representing *ABL1* at 9q34 and two green signals representing *BCR* at 22q11.2 are seen, whereas in the leukemia cells **(B)**, one orange signal (the normal 9q34), one green signal (the normal 22q11.2), and two orange-green (yellow) fusion signals representing der(9q) and der(22q) are detected. Courtesy Dr. Yanming Zhang, University of Chicago.

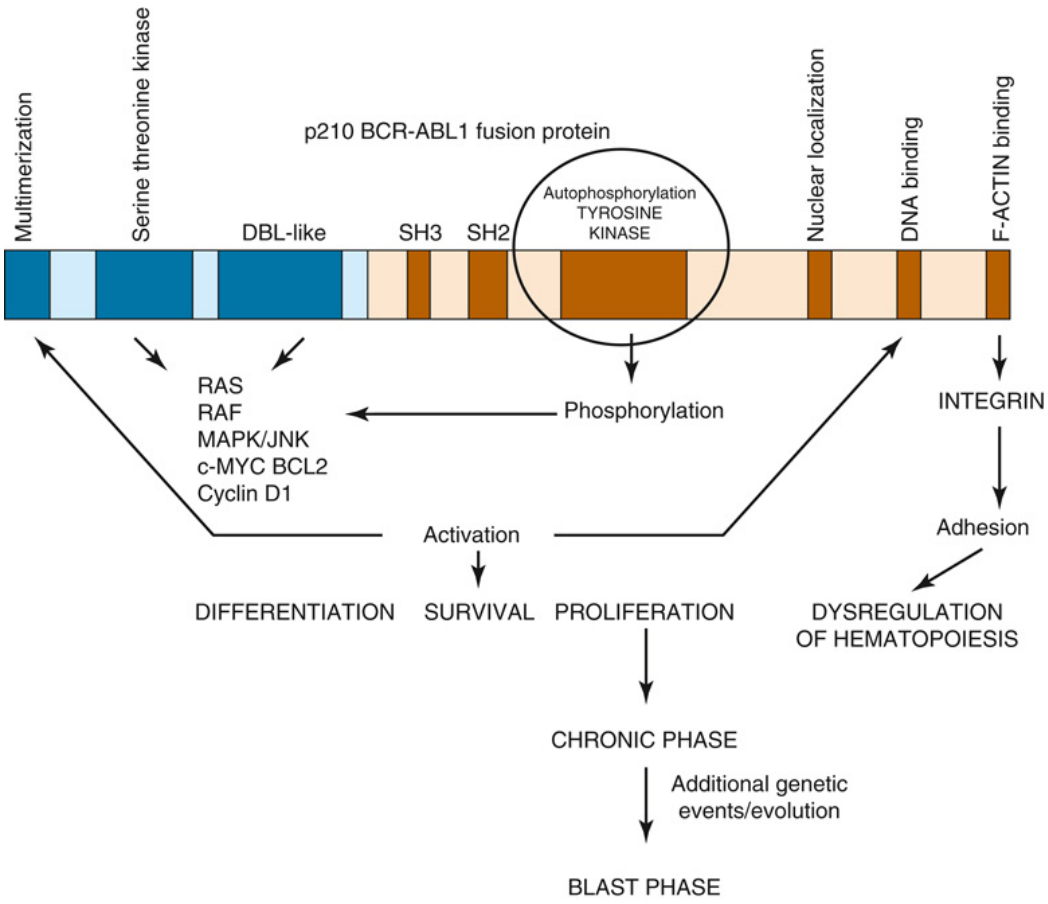

FIGURE 47-4 *BCR*::*ABL1* fusion on chromosome 22 leads to a BCR::ABL1 fusion protein with a constitutively activated tyrosine kinase in a domain of the protein encoded by *ABL1*. This tyrosine kinase plays a pivotal role in the pathogenesis of chronic myeloid leukemia and leads to autophosphorylation of other sites on the oncoprotein. These serve as sites of phosphorylation of cellular proteins involved in pathways of differentiation, survival, proliferation, cellular adhesion, and regulation of hematopoiesis.

Table 47-1

Rare = <3%.

CML, CP, chronic myeloid leukemia, chronic phase; *CNL,* chronic neutrophilic leukemia; *ET,* essential thrombocythemia; *PMF,* primary myelofibrosis; *PV,* polycythemia vera.

* In 5% to 10% of patients with CML, cryptic or complex rearrangements result in *BCR*::*ABL1* fusion gene, although no Ph chromosome is detected in the karyotype.[43,179,232]

An activating mutation of *CSF3R,* located at chromosome 1p34.3, that encodes the CSF3R, has been reported as the driver mutation in CNL and in occasional cases of myelodysplastic/myeloproliferative neoplasm (MDS/MPN) atypical CML (aCML).[36,48,49] The extracellular domain of CSF3R includes a membrane proximal region important for granulocytic proliferation, whereas a cytoplasmic region is important for regulation of granulocytic differentiation and function. The mutation commonly associated with CNL, *CSF3R* T6181, is an activating mutation in the membrane proximal region that results in dimerization of the receptor with ligand independence and activation of the JAK-STAT pathway.[36,50] Of interest is that mutations encoding the distal cytoplasmic tail of *CSF3R* are found in approximately 40% of cases of severe congenital neutropenia, which does not have an inherent tendency to progress to leukemia. However, patients with severe congenital neutropenia who are treated with the growth factor GCSF are at risk for development of acute myeloid leukemia (AML); if leukemia occurs, it is often associated with a second mutation of *CSF3R* identical to that observed in CNL.[50]

Associated Mutations, Cytogenetic Abnormalities, and Pathogenetic Mechanisms in Myeloproliferative Neoplasms

In addition to the major MPN-related driver genetic abnormalities already listed, whole exome/genome studies have revealed mutations of genes affecting numerous cellular pathways in MPNs. These mutations are not specific for or restricted to MPNs but are likely to be important in cooperating with the driver mutations to influence the disease phenotype and prognosis. The most commonly affected genes are those important in epigenetic regulation *(TET2, ASXL1, EZH2, IDH1, IDH2, DNMT3A)*, RNA splicing *(SF3B1, SRSF2, SETBP1)*, or transcriptional mechanisms *(TP53, IKZF1, NFE2, CUX1)*.[42,43,51-55] These gene mutations are not mutually exclusive, and more than one can exist simultaneously in neoplastic cells. Their frequency depends on the MPN subtype and the stage of disease; they tend to be more common in patients with progressive disease. New karyotypic abnormalities also often emerge in the course of the disease and are predictors of worse prognosis. Finally, many of the *BCR*::*ABL1*-negative MPNs (particularly PMF) have an inflammatory component resulting from the production and release of numerous cytokines from neoplastic and nonneoplastic cells that contribute to the clinical and pathologic findings, although the reason for this abnormal cytokine milieu is not well understood.[56]

Chronic Myeloid Leukemia (CML)

Definition

CML is an MPN harboring the *BCR*::*ABL1* gene in which granulocytes predominate in the blood and bone marrow. It arises in

an abnormal hematopoietic stem cell (leukemic stem cell) and is characterized by the t(9;22)(q34.1;q11.2) chromosomal translocation, which results in the formation of the Ph chromosome that contains the *BCR*::*ABL1* fusion gene. The fusion gene (invariably present in CML) encodes an abnormal oncoprotein, BCR::ABL1, with constitutively activated TK activity that is central to the pathogenesis of CML.[15,16] Granulocytes are the major proliferative component, but all myeloid lineages and some lymphoid and endothelial cells carry the abnormal gene.[57,58] The natural history of untreated CML is biphasic or triphasic: an initially chronic phase (CP) is followed by an accelerated phase (AP), a BP, or both. Though the ICC retains the three phases of CML, the AP is no longer included in the proposed WHO 5th edition.[2]

The diagnosis of CML requires detection of the Ph chromosome or *BCR*::*ABL1* fusion gene in the appropriate clinical and laboratory setting. The National Comprehensive Cancer Network (NCCN) practice guidelines recommend that, in addition to a thorough clinical history and physical examination, the workup of CML include a complete blood count with leukocyte differential and chemistry profile.[59] A bone marrow aspiration is necessary to obtain material for a complete karyotype and for morphologic evaluation to assess the phase of disease. A bone marrow trephine biopsy is indicated for patients who meet any of the criteria for AP (CML-AP) or BP (CML-BP) and for patients who have a clinical history suggestive of disease progression (e.g., progressive splenomegaly).[1] Although not required for diagnosis, a bone marrow biopsy can be helpful to evaluate for the presence and degree of marrow fibrosis. In addition, fluorescence in situ hybridization (FISH) studies to detect

the *BCR*::*ABL1* fusion gene and quantitative reverse transcriptase polymerase chain reaction (RT-PCR) for baseline measurement of *BCR*::*ABL1* transcripts are necessary for disease monitoring. The major findings of CML-CP are listed in **Box 47-2**.

Synonyms and Related Terms

Chronic myelogenous leukemia; chronic granulocytic leukemia; chronic myelocytic leukemia

Epidemiology

Although CML has an annual incidence of only 1 or 2 per 100,000 persons,[60,61] it is one of the most thoroughly studied of all hematopoietic neoplasms. The development of TKIs that block the TK activity of *BCR*::*ABL1* has markedly improved survival, so the prevalence of CML is increasing and predicted to exceed that of chronic lymphocytic leukemia, AML, and lymphoblastic leukemia combined in the next 2 to 3 decades.[62,63]

Box 47-2 Common Features of the Chronic Phase of Chronic Myeloid Leukemia

Annual Incidence

- 1 or 2 per 100,000 individuals

Age

- Any, median age about 65 years; pediatric cases rare

Clinical Findings

- Fatigue
- Weight loss
- Fever
- Splenomegaly
- Nearly 50% of patients are asymptomatic at initial diagnosis

Blood Findings

- Leukocytosis
- Platelets normal or increased
- Anemia often present
- Spectrum of maturing granulocytes with a “myelocyte bulge”
- Blasts usually <2% of white blood cells
- Absolute basophilia
- No significant dysplasia

Bone Marrow Findings

- Hypercellularity
- Increased myeloid-to-erythroid ratio
- Blasts usually <5%, always <10%
- Widening of cuff of immature granulocytes around bone trabeculae
- Spectrum of maturing granulocytes with myelocyte bulge but no dysplasia

- Megakaryocytes normal or increased in number, but with "dwarf" morphology
- Reticulin fibers normal to moderately increased

Genetics

- 100% have Philadelphia chromosome or *BCR*::*ABL1* fusion gene

Clinical Findings

The median age at diagnosis is 65 years, but CML can occur at any age, including childhood.[60,64,65] The age at onset is reportedly lower in regions of lower socioeconomic conditions.[61] There is a slight male predominance. Most patients are diagnosed in CP, which has an insidious onset. Nearly 50% of newly diagnosed patients are asymptomatic and discovered when an abnormal white blood cell (WBC) count is found during a routine medical examination.[60,66] When symptoms are present, they include fatigue, malaise, weight loss, night sweats, and symptoms related to anemia. Palpable splenomegaly is present in about 50% of patients and may be associated with early satiety; hepatomegaly may also be present. Significant lymphadenopathy is uncommon, and if present, a lymph node biopsy should be considered to exclude blastic proliferation in the node. About 5% of patients initially present in AP or BP without a previously recognized CP.[60]

Morphologic Findings

Peripheral Blood, Chronic Phase

In CML-CP, the peripheral blood shows leukocytosis (12–1000 × 10^9/L; median, ≈80 × 10^9/L).[60,66] Children, however, typically have a higher WBC count (median, ≈250 × 10^9/L).[64,65] The leukocytosis is caused by neutrophils in different stages of maturation, with peaks in the percentages of myelocytes and segmented neutrophils (**Fig. 47-5**). Significant dysplasia is absent. Blasts usually account for less than 2% of the WBCs. Absolute basophilia and eosinophilia are common. Although the absolute monocyte count may be elevated (>1 × 10^9/L), the percentage of monocytes is generally less than 3%.[60,67] In most cases, the platelet count is mildly or moderately elevated; however, in 10% to 15% of patients, it is in excess of 1000 × 10^9/L. Marked thrombocytopenia is unusual. Anemia is common, but hemoglobin values of less than 10 g/dL are initially present in only a minority of cases. Occasional patients are seen with findings that do not fit the classic presentation and that can suggest a different diagnosis, such as a normal or only modestly elevated WBC count but marked thrombocytosis (mimicking ET)[68,69] or leukocytosis composed almost exclusively of segmented neutrophils (resembling CNL).[70] In some cases, monocytes are substantially increased, and the case resembles chronic myelomonocytic leukemia (CMML).[71] These unusual presentations of CML often correlate with variations in the size of the BCR::ABL1 fusion protein caused by varying breakpoints within the *BCR* gene[72] (see the subsection, Cytogenetics/Molecular Findings).

Bone Marrow, Chronic Phase

The peripheral blood findings, when combined with molecular genetic studies (FISH, PCR) to detect *BCR*::*ABL1,* are often

diagnostic, but a bone marrow aspirate is essential to provide adequate material for a complete karyotype and to assess marrow morphology to determine the phase of disease. A bone marrow biopsy is not required for diagnosis in every case but should be obtained if the blood findings are atypical or the bone marrow cannot be aspirated. In addition, bone marrow fibrosis should be evaluated, as even mild fibrosis at diagnosis correlates with a decreased major molecular response (MMR) rate in the first year of TKI therapy.[73]

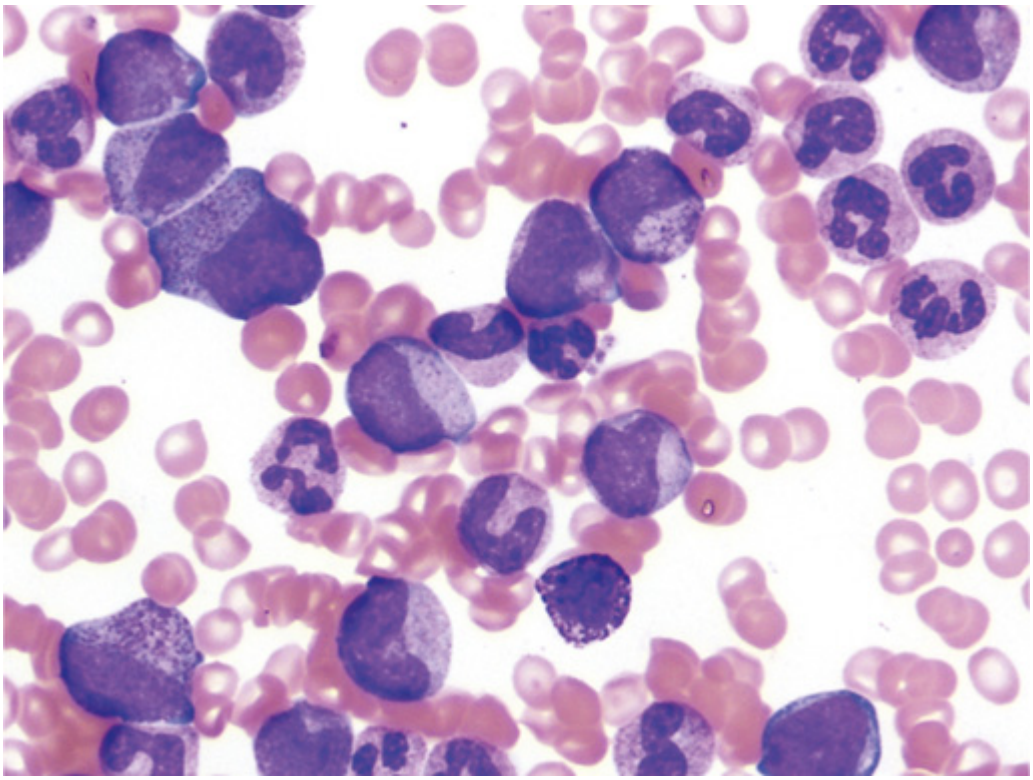

FIGURE 47-5 Peripheral blood smear of a patient with chronic myeloid leukemia illustrates marked leukocytosis with a spectrum of neutrophil maturation, including a prominence of myelocytes and segmented neutrophils. Basophils are invariably increased in absolute numbers.

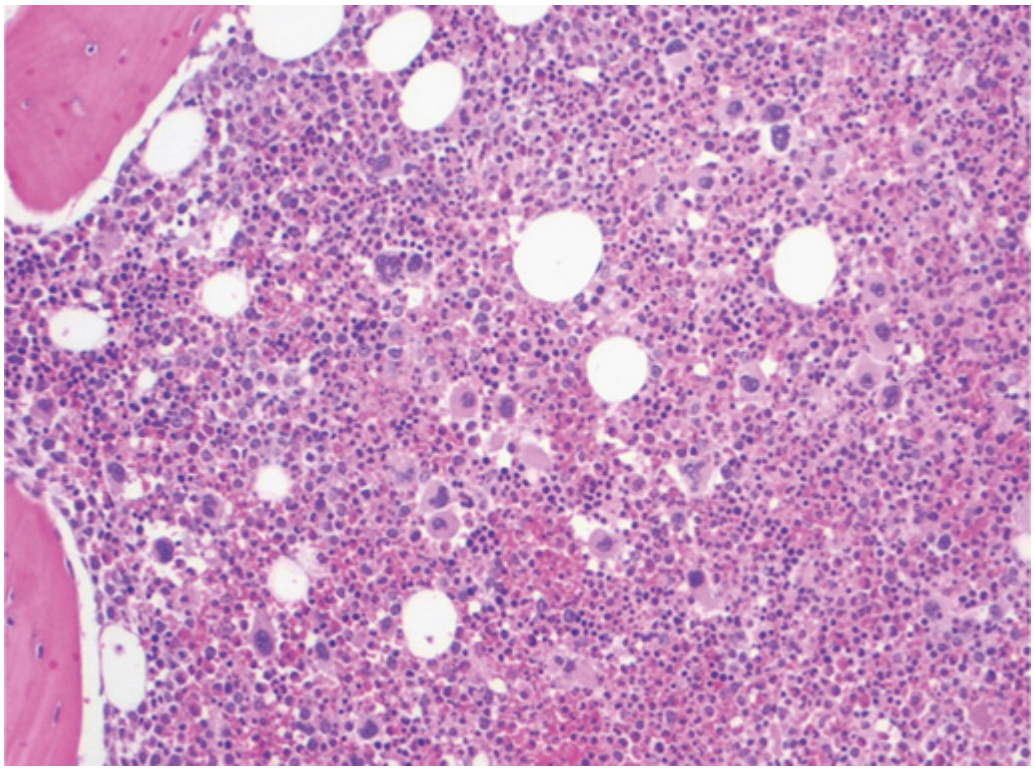

FIGURE 47-6 The bone marrow in the chronic phase of chronic myeloid leukemia is hypercellular. It shows granulocytic proliferation, with small islands of erythroid precursors interspersed and increased numbers of megakaryocytes, many of which are “dwarf” megakaryocytes.

Bone marrow specimens in untreated CP are hypercellular as a result of marked granulocytic proliferation (**Fig. 47-6**), which shows a maturation pattern similar to that in the blood with expansion of the myelocyte and segmented neutrophil stages.[74] There is no significant dysplasia[75] (**Fig. 47-7**). Blasts typically account for less than 5% of the marrow cells; 10% or more blasts indicate disease progression to AP.[76] Erythroid precursors are reduced in percentage but show normal maturation. Basophils and eosinophils are

frequently conspicuous. Histiocytes resembling Gaucher cells or “sea blue” histiocytes are commonly observed (**Fig. 47-8**) and attributed to an excess of phospholipids from the increased cellular burden and cell turnover. These “pseudo-Gaucher” histiocytes carry *BCR*::*ABL1* because they are progeny of the affected leukemic stem cell.[77] Megakaryocytes may be normal or decreased in number, but 40% to 50% of cases exhibit moderate to marked megakaryocytic proliferation (**Fig. 47-9**). In CP, the megakaryocytes are smaller than normal and tend to have hypolobated nuclei (i.e., “dwarf megakaryocytes”).[78] However, they are not true “micromegakaryocytes,” such as those found in myelodysplastic syndromes (MDS). In CML, the finding of significant numbers of MDS-like micromegakaryocytes should raise concern for disease progression.

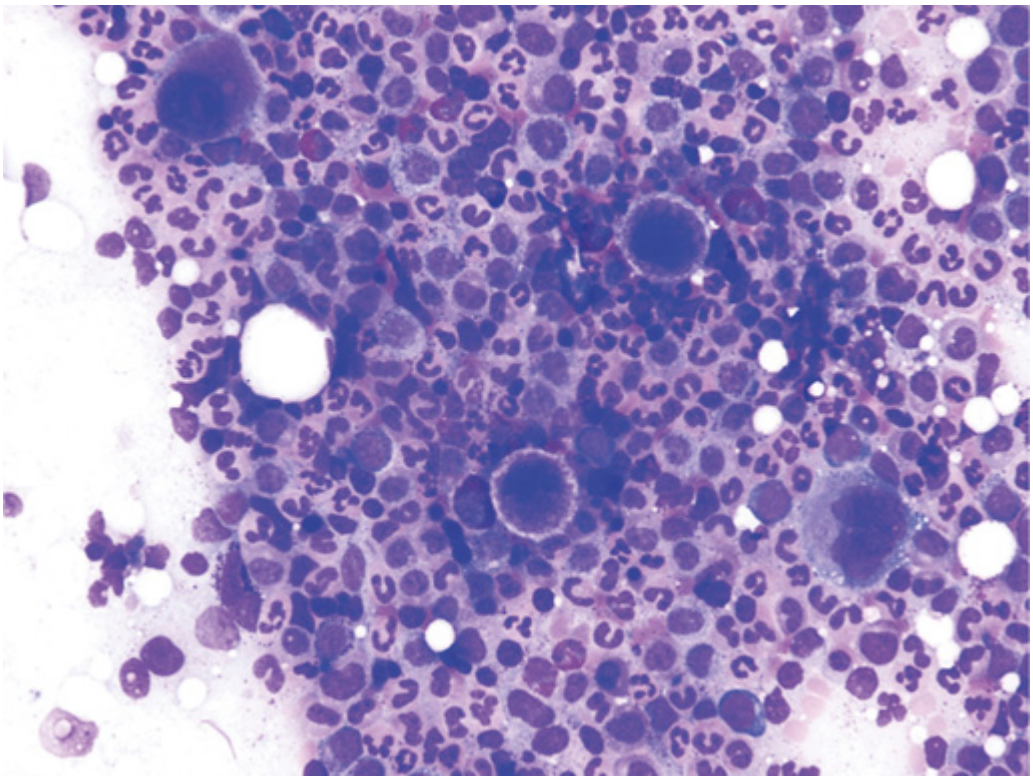

FIGURE 47-7 Bone marrow aspirate smear from a patient with chronic myeloid leukemia, chronic phase.

In marrow biopsy sections, a 5-cell to 10-cell–thick layer of immature granulocytes is common around bone trabeculae (**Fig. 47-10**), compared with the 2-cell or 3-cell–thick layer normally present.[74,78] Granulocytic maturation proceeds toward the center of the intertrabecular spaces. A modest number of blasts may be seen immediately adjacent to the bone and scattered among the maturing cells, but sizable clusters of blasts are not present in CP, although focal aggregates of myelocytes are not uncommon. Moderate to marked reticulin fibrosis is seen in 30% to 40% of biopsies at diagnosis, sometimes accompanied by increased numbers of megakaryocytes and splenomegaly.[79]

Extramedullary Tissues

In CP, the spleen is variably enlarged because of infiltration of the red pulp cords by granulocytes. A similar infiltrate is seen in the hepatic sinuses and occasionally in lymph nodes. These extramedullary infiltrates are composed of a mixture of immature and mature granulocytes; any significant shift toward immaturity with an increased percentage of blasts (≥10%) indicates progressing or transformed disease. In BP (≥20% blasts), any extramedullary tissue can be infiltrated, but the spleen, liver, lymph node, skin, and soft tissues are most commonly involved.[74] In CML, regardless of blood and marrow findings, clinical evidence of an infiltrative process in any extramedullary site should be investigated to exclude BP.

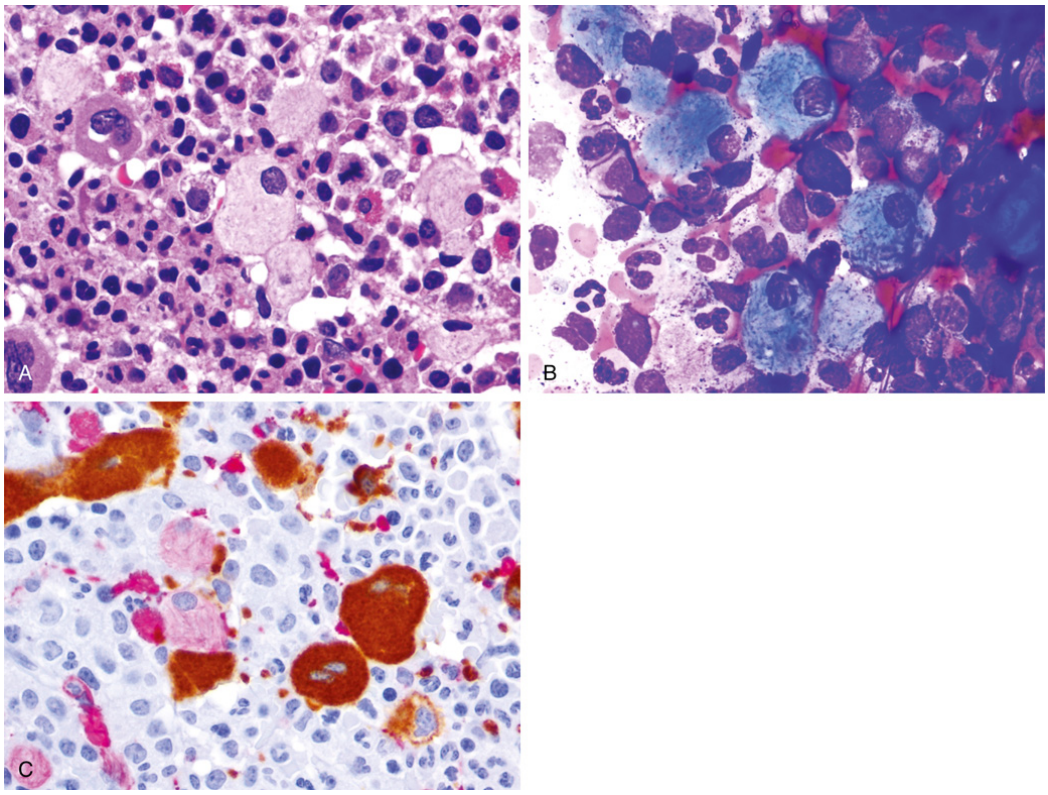

FIGURE 47-8 Gaucher-like cells in chronic myeloid leukemia.A, These cells can be appreciated in bone marrow biopsy sections as foamy cells with striated cytoplasm. **B,** In aspirate smears, they appear as blue-pigmented cells. **C,** Immunohistochemistry with a dual stain for CD68 *(pink)* and CD61 *(brown)* nicely demonstrates Gaucher-like histiocytes and small megakaryocytes, respectively. Courtesy Dr. Elizabeth Hyjek.

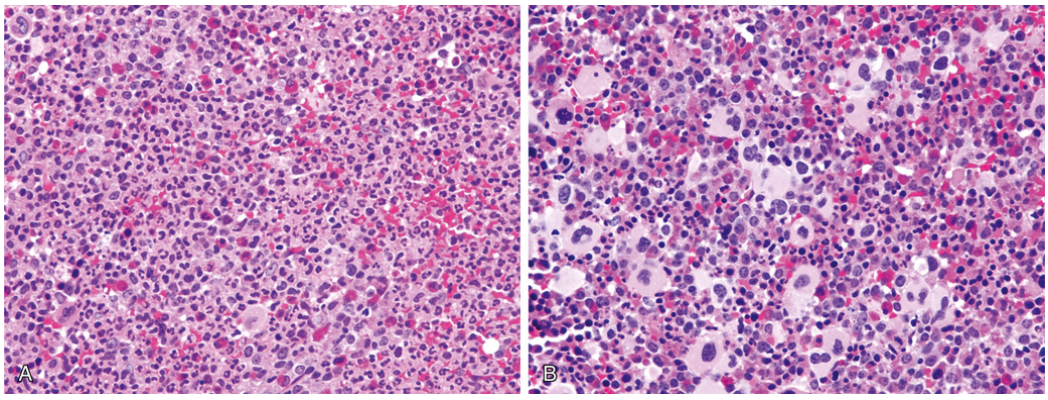

FIGURE 47-9 The number of megakaryocytes in chronic myeloid leukemia (CML) varies, from cases with mainly granulocytic proliferation and few megakaryocytes **(A)** to cases with substantially increased megakaryocytes **(B)**.

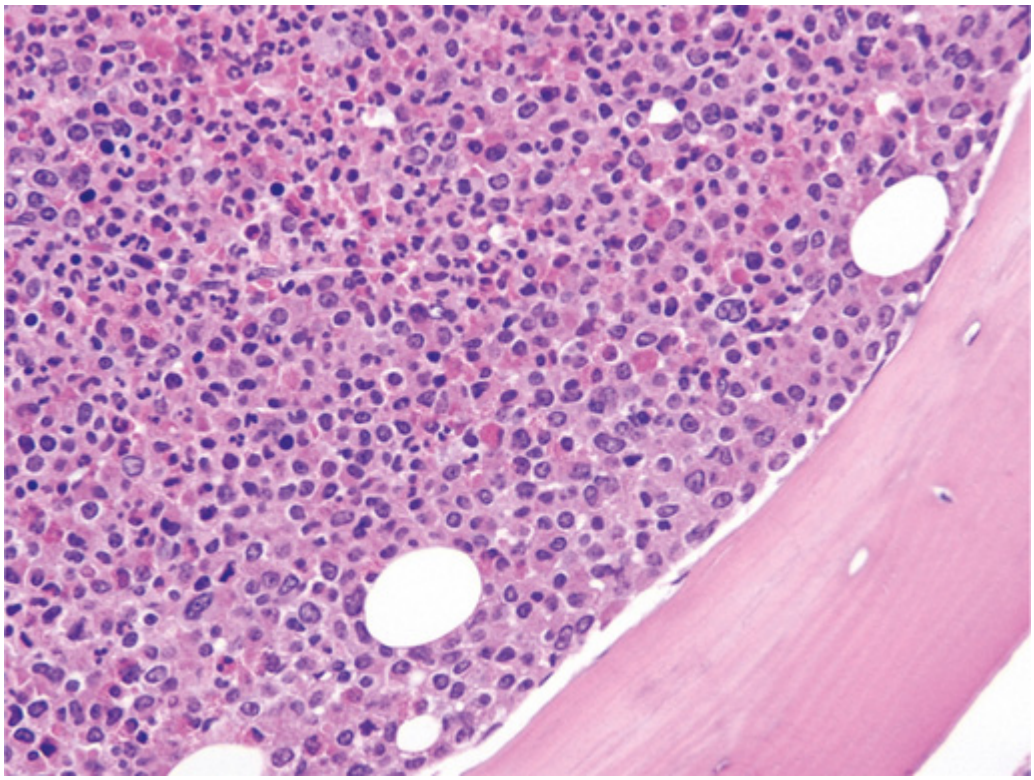

FIGURE 47-10 In chronic myeloid leukemia, the peritrabecular rim of immature granulocytes is thickened from the normal two-cell or three-cell layer to five or more cells, with mature cells farther from the bone in the intertrabecular region.

Immunophenotype

Immunophenotypic analysis of the granulocytes contributes little to the diagnosis of CML-CP, although reportedly, the expression of CD7 on CD34-positive cells in the blood or bone marrow has adverse prognostic significance, whereas a normal CD34-positive stem cell population that lacks any abnormal markers, such as CD7, CD56, or CD11b, predicts a better response to TKI therapy.[80-82]

Cytogenetics/Molecular Findings

All patients with CML have the t(9;22)(q34;q11.2) abnormality, which results in the *BCR*::*ABL1* fusion gene.[16] In 90% to 95% of cases, this reciprocal chromosomal translocation is recognized on routine karyotype as the Ph chromosome, der(22)t(9;22). In the remaining cases, the rearrangement of genetic material may be complex (involving one or more additional chromosomes) or is cryptic and not identified by routine cytogenetic analysis but detected instead by FISH or RT-PCR analyses.[25] This fusion gene is necessary and sufficient to cause CML through its constitutive activation of multiple signal transduction pathways.

The Ph chromosome is not specific to CML but is also present in 15% to 30% of adults and 5% of children with B-lymphoblastic leukemia, in some cases of mixed phenotype acute leukemia, and in rare cases of AML. The site of the breakpoint in *BCR* (**Fig. 47-11**) determines the phenotype of the disease associated with the translocation.[72] In 95% of cases of CML and 25% to 30% of cases of Ph-positive acute lymphoblastic leukemia (ALL), the breakpoint is in the major breakpoint cluster region, spanning exons 12 to 16, and an abnormal fusion protein, p210, is formed. Rarely, the breakpoint in *BCR* occurs in the mu breakpoint region, spanning exons 17 to 20, and a larger fusion protein, p230, is formed. Patients with the p230 protein usually demonstrate marked peripheral blood neutrophilia or thrombocytosis.[70] Breaks in the minor breakpoint region result in a short fusion protein (p190) that is usually associated with Ph-positive ALL, although small amounts of the p190 transcript can be detected in most patients with CML because of alternative splicing of the *BCR* gene.[72,83] The short p190 transcript is also found in rare

cases of CML with increased numbers of monocytes that resemble CMML.[71] Cases with the p230 or p190 variant breakpoint exhibit other morphologic features of CML, such as basophilia and small megakaryocytes with hypolobated nuclei.

Although the *BCR*::*ABL1* fusion gene may be detected by FISH or PCR in blood or marrow cells, a complete karyotype is mandatory at the time of diagnosis. The Ph chromosome is often the sole cytogenetic abnormality at diagnosis, but additional karyotypic abnormalities may be present in the same clone. If, at diagnosis, any of the "major route" karyotypic abnormalities (+8, +19, isochromosome 17q, extra Ph chromosome) are present in addition to the Ph chromosome, the patient should be considered as presenting in AP. If these or any other additional chromosomal abnormalities appear in subsequent specimens, they indicate disease progression.[84]

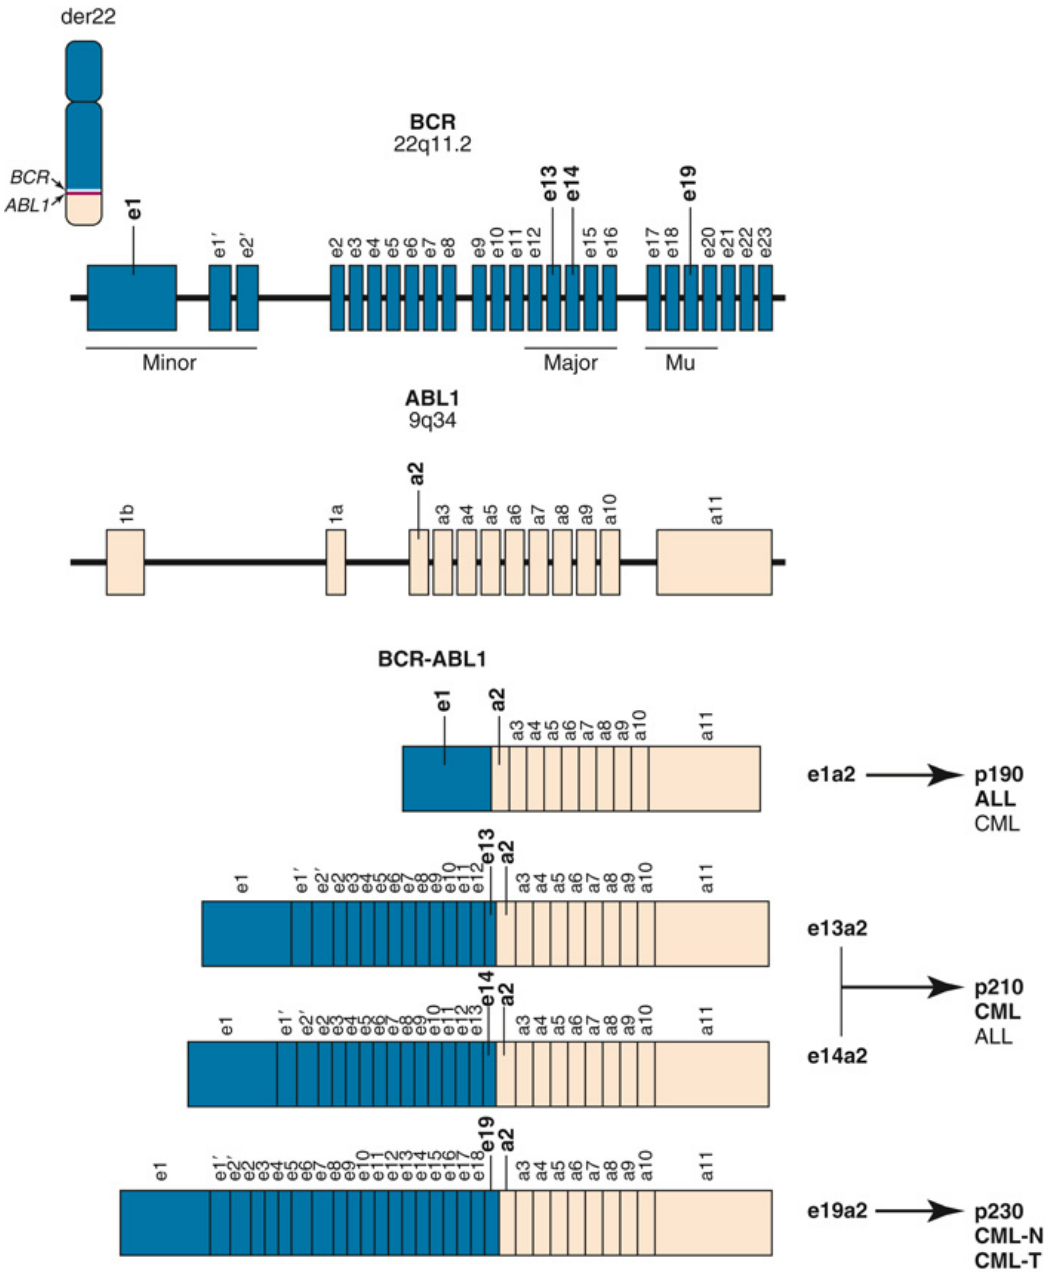

FIGURE 47-11 Schematic representation of the *BCR* gene *(blue)* and *ABL1* gene *(cream)* and their breakpoints in t(9;22)(q34;q11.2). Breakpoints in *ABL1* generally occur upstream of exon 2a, either between 1b and 1a or between 1a and 2a. The breakpoints in *BCR* are variable and can occur in the minor

breakpoint cluster region, giving rise to the e1a2 fusion; the major breakpoint cluster region, fusing either e13 or e14 with a2; or the mu breakpoint region, leading to an e19a2 fusion. These varying breakpoints result in different-sized fusion proteins that correlate with disease phenotype. Almost all cases of chronic myeloid leukemia (CML) are associated with breakpoints in the major breakpoint cluster region that result in the p210 protein, although some cases of Ph-positive acute lymphoblastic leukemia (ALL) exhibit this breakpoint as well. The minor breakpoint, e1a2, gives rise to the p190 protein; it is seen in more than 50% of Ph-positive ALLs and only rarely in CML, in which case it is associated with monocytosis, mimicking chronic myelomonocytic leukemia. Breaks in the mu region lead to the p230 protein, which is associated with CML with excessive neutrophils or excessive thrombocytosis.

The significance of mutations of genes involved in epigenetic regulation, translational mechanisms, or RNA splicing is not yet clear in CML-CP. Mutations of *ASXL1, DNMT3A, RUNX1,* and *TET2* are reportedly present in some newly diagnosed CML patients in the few series reported to date, but their influence on disease features is not yet known. Of interest, in rare cases, mutations have been found in Ph-positive and Ph-negative clones simultaneously, raising the

possibility that the mutation preceded the acquisition of *BCR*::*ABL1*.[51-53]

In patients who progress to AP or BP, the genetic landscape changes remarkably as additional chromosomal and submicroscopic genetic aberrations occur and accumulate to disrupt maturation and to drive uncontrolled proliferation.

Clinical Course

In the absence of effective therapy, patients with CML will invariably demonstrate disease progression. In some, the progression is characterized by gradual but persistent deterioration in hematologic parameters and performance status (i.e., AP), which may result in death or show yet further evolution to overt BP. Other patients progress directly from CP to BP, which is characterized by 20% or more blasts in the blood or bone marrow or by a proliferation of blasts in an extramedullary site. Disease progression is invariably associated with additional genetic abnormalities.

Recognition of disease progression is important, but the clinical and morphologic boundaries among CP, AP, and BP are not sharp, and the parameters to define these phases vary among different guidelines. Furthermore, gene expression profiles of AP and BP are similar, with changes in the expression profile occurring late in CP or early in AP, before clinical or morphologic evidence of overt progression.[84] It should be noted that 20% to 30% of patients receiving TKI therapy have apparent disease progression caused by acquired mutations in *BCR*::*ABL1* that affect the TK binding domain and thus affect alterations in the binding site of the oncoprotein, rendering the TKI ineffective.[59,85] To date, more than 90 such

mutations have been described that confer TKI resistance. Less commonly, subclones of leukemic cells with amplification of *BCR*::*ABL1* or mutations in the SH3-SH2 domain result in disease progression, or there may be genetic alterations that occur in the *BCR*::*ABL1*-independent signaling pathways.[86,87] In patients in CP with TK domain mutations or *BCR*::*ABL1* amplification, disease progression may be circumvented or reversed by increasing the dosage or switching to a newer-generation TKI. A new class of small molecules targeting the myristoyl pocket of ABL1 has been introduced into the treatment of CML.[88,89]

The genetic events responsible for evolution into AP or BP are largely unknown, although nearly 80% of patients with advanced disease have additional chromosomal abnormalities including +8, i(17q), +19, and an extra Ph chromosome, suggesting that additional genetic "hits" likely induce transformation.[74,84] Though *ASXL1* mutations may be present in CP, patients with *ASXL1* mutations acquire other additional variants during progression to BP, including *RUNX1, TP53, BCOR,* and *SETD1B*.[90]

Accelerated Phase

In accordance with the ICC guidelines, AP is defined by 10% to 19% bone marrow or peripheral blood blasts, peripheral blood basophilia ≥20%, or the identification of additional clonal cytogenetic abnormalities in Ph-positive cells, i.e., second Ph, +8, i(17q), +19, complex karyotype, or abnormalities of 3q26.2.[1] In the proposed WHO 5th edition, however, AP at diagnosis or during treatment has been omitted; only the CP and BP are recognized.[2]

Bone marrow specimens of patients with AP may show variable cellularity, and there may be dysplastic features in the granulocytic and other myeloid lineages.[75] An increase in myeloid lineage blasts (10% to 19%) may be appreciated on aspirate smears or in biopsy sections (Figs. **47-12** and **47-13**), in which they can be highlighted with immunohistochemical stains for CD34. Sizable clusters of megakaryocytes are sometimes seen, including true micromegakaryocytes similar to those in MDS, often associated with significant reticulin or collagen fibrosis.[76] Lymphoid blasts may be seen in AP, but any bona fide lymphoblasts in the blood or bone marrow, even during CP, should raise concern of an imminent lymphoblastic crisis, as lymphoblastic BP is reported to sometimes have an abrupt onset and usually lacks a preceding AP.[91,92]

Blast Phase

The ICC guidelines have maintained a blast percentage threshold of at least 20% in the blood or bone marrow to establish a diagnosis of CML-BP.[1] Increasing numbers of lymphoblasts (>5%) in peripheral blood or bone marrow indicate impending lymphoid BP and thus should prompt further laboratory and genetic studies.[91] Of note, other classification and risk stratification systems that include the International Blood and Marrow Transplant Registry, MD Anderson Cancer Center, and European Leukemia Net have defined a higher blast threshold of more than 30% for BP and are frequently used for eligibility criteria in clinical trials.[59,93,94]

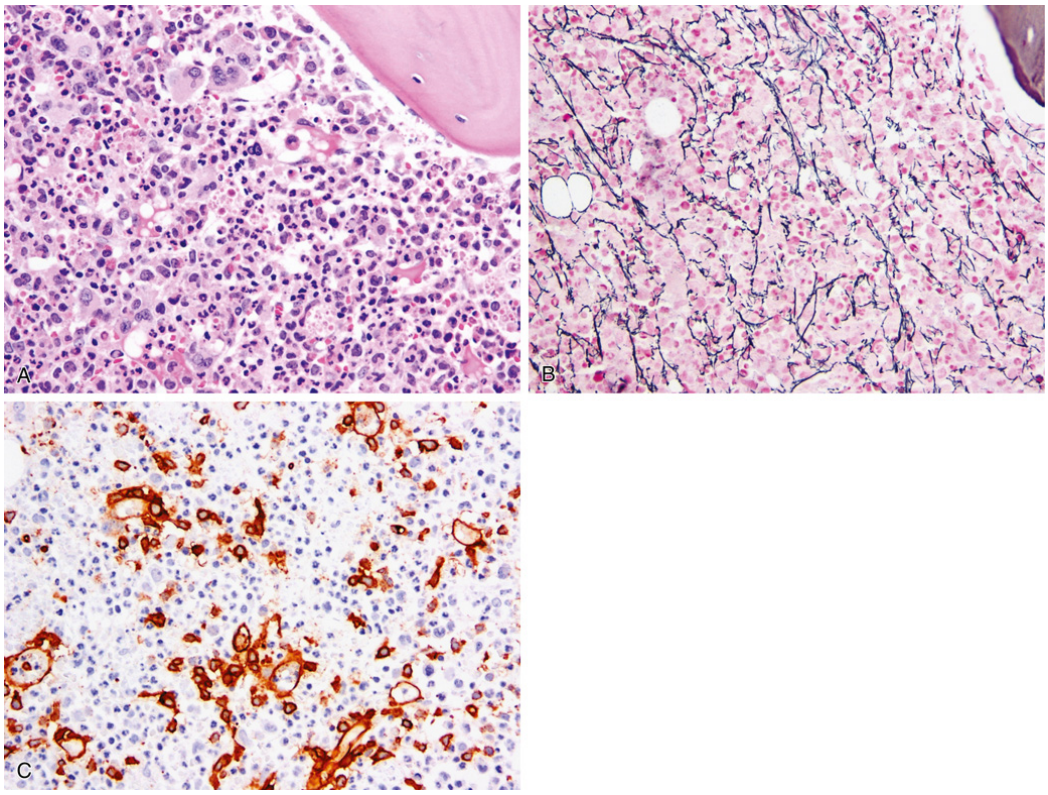

FIGURE 47-12 CML, accelerated phase. This patient, who had Ph-positive CML for 5 years, developed cytopenia in the blood with 12% blasts. The bone marrow biopsy specimen is hypercellular **(A)**, with reticulin fibrosis **(B)**. An immunohistochemical stain for CD34 **(C)** reveals more blasts than were appreciated in the hematoxylin-eosin–stained section.

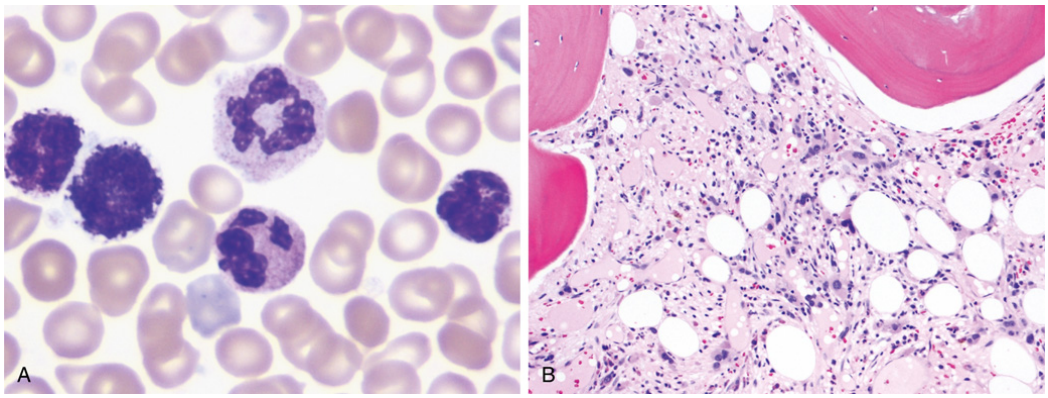

FIGURE 47-13 CML, accelerated phase.A, This patient with chronic myeloid leukemia had more than 20% basophils in the blood. **B,** The bone marrow biopsy shows marked fibrosis and atypical megakaryocytic proliferation.

The ICC and proposed WHO 5th edition criteria for BP include the finding of 20% or more blasts in the blood or bone marrow and an extramedullary proliferation of blasts that disrupts the architecture of the infiltrated tissue (**Box 47-3**). In addition, if blasts occupy focal but significant areas of the bone marrow, such as an entire intertrabecular space, a presumptive diagnosis of BP is warranted, even if the remainder of the marrow shows CP.[76]

In the majority of BP cases, the blasts are of myeloid lineage (neutrophilic, monocytic, megakaryocytic, basophilic, eosinophilic, erythroid blasts, or any combination thereof) (**Fig. 47-14**); but 20% to 30% of cases are composed of lymphoblasts that are usually of B-cell origin, although cases of T-lymphoblastic and NK-cell transformation have been reported[95] (**Fig. 47-15**). Sequential lymphoblastic and myeloblastic crises may also occur. The origin of the blasts is often morphologically obvious, but sometimes, the blasts are primitive or heterogeneous, and mixed-phenotype cases are

common; thus, immunophenotypic analysis, preferably by multiparameter flow cytometry, is recommended. In myeloid BP, the blasts have strong, weak, or no myeloperoxidase activity but express one or more antigens associated with granulocytic, monocytic megakaryocytic, or erythroid differentiation (e.g., CD33, CD13, CD14, CD11c, CD11b, CD117, CD15, CD41, CD61, CD71, glycophorin A or C). However, in many cases of myeloid origin, the blasts also express one or more lymphoid-related antigens. Most lymphoblastic cases are precursor-B in origin and express terminal deoxynucleotidyl transferase in addition to B-related antigens (CD19, CD10, CD79a, PAX5, CD20), but a minority of cases express T-cell–related antigens (CD3, CD2, CD5, CD4, CD8, CD7).[96,97] Expression of one or more myeloid-related antigens is common in B-cell and T-cell–derived BPs. An increased incidence of unusual immunophenotypes and types of blasts (e.g., basophil blasts, megakaryoblasts) has been described in the era of TKIs.[98] Rare cases of myeloid BP have cytogenetic abnormalities in which a specific recurring chromosomal rearrangement associated with AML, such as inv(16)(p13.1q22) or t(16;16)(p13.2;q22), is found in the same cells as the Ph chromosome (**Fig. 47-14**). In such cases, however, these chromosomal abnormalities, often associated with favorable outcomes in AML, reportedly have no favorable effect when found with the Ph chromosome.[99]

Therapy, Disease Monitoring, and Prognosis

The development of TKIs that target the constitutively activated TK domain of the BCR::ABL1 fusion protein is a remarkable advance that led to dramatic improvements in survival and quality of life in

patients with CML.[100] Now, most patients with newly diagnosed CML can be expected to live a nearly normal life span if treated with TKI therapy.

The key to the success of TKI therapy is regular and continual assessment of the hematologic, cytogenetic, and molecular status of the patient to detect changes indicative of drug failure or resistance. In general, hematologic and genetic monitoring once every 3 months is recommended, depending on the response to the TKI. The morphologic features in blood and bone marrow specimens of patients receiving TKI therapy reflect the changes in the cytogenetic and molecular events as the patient responds (**Fig. 47-16**), with normalization of the WBC count and return to a cellular bone marrow with relatively normal morphology, usually during a period of 3 to 6 months.[101] Although morphologic features are not sensitive enough to reflect early increases in the burden of the *BCR*::*ABL1* transcript that usually indicate drug resistance, the persistence or reappearance of any morphologic features indicative of CML in follow-up specimens of patients receiving TKI therapy should raise concern for drug resistance and prompt further evaluation of the cytogenetic or molecular status. In the current age of TKI therapy, the most important prognostic indicator is the response to therapy at the hematologic, cytogenetic, and molecular levels.

Box 47-3 Diagnostic Criteria for Accelerated and Blast Phase Chronic Myeloid Leukemia (CML) According to International Consensus Classification

ACA, Additional chromosome abnormality; *Ph,* Philadelphia chromosome.

Accelerated Phase

- Bone marrow or peripheral blood blasts 10% to 19%
- Peripheral blood basophils ≥20%
- Presence of additional clonal cytogenetic abnormality in Ph-positive cells (ACA)
    - Second Ph, trisomy 8, isochromosome 17q, trisomy 19, complex karyotype, or abnormalities of 3q26.2

Blast Phase

- Bone marrow or peripheral blood blasts ≥20%
- Myeloid sarcoma, extramedullary blast proliferation
- Bone marrow or peripheral blood lymphoid blasts >5% is consistent with lymphoblastic crisis
    - Immunophenotypic analysis is required to confirm lymphoid lineage

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

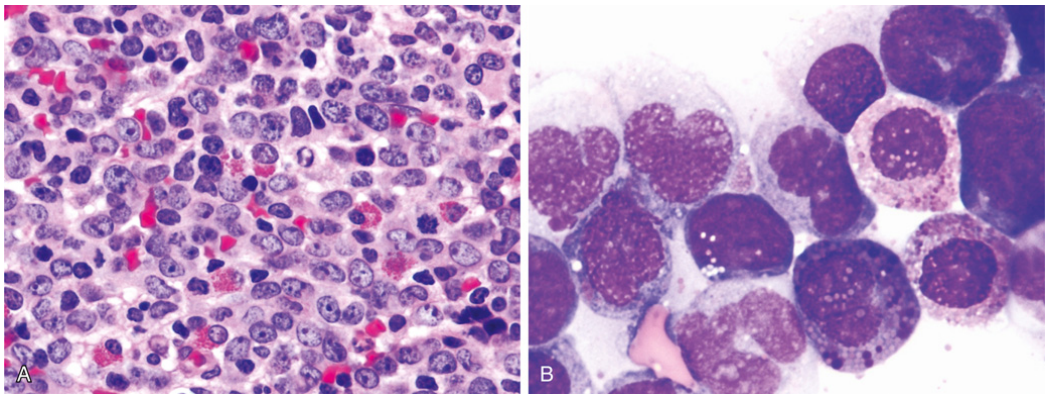

FIGURE 47-14 Chronic myeloid leukemia, myeloid blast phase.A, Bone marrow biopsy shows sheets of blasts with some eosinophils intermixed. **B,** Marrow aspirate contains abnormal eosinophils and monocytic cells. This patient's leukemic cells showed t(9;22)(q34;q11.2) plus inv(16)(p13.1q22).

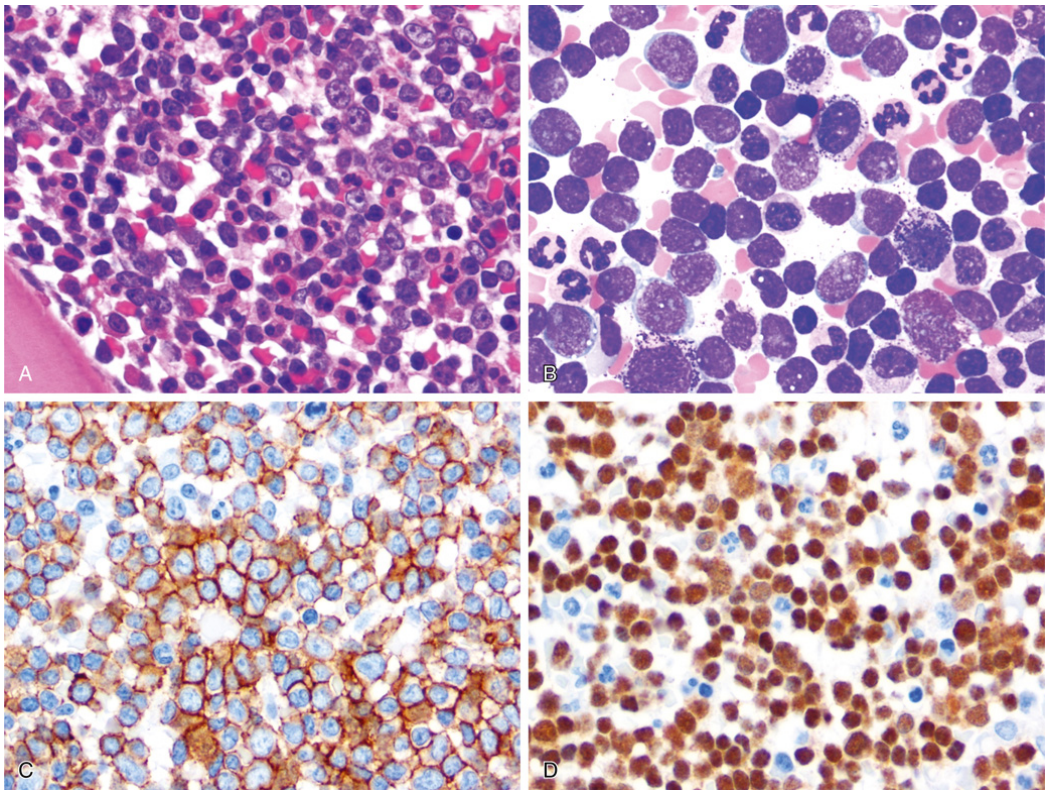

FIGURE 47-15 Chronic myeloid leukemia (CML), lymphoid blast phase. Bone marrow biopsy **(A)** and aspirate **(B)** show increased blasts with lymphoid morphology in a background of granulocytic cells. The blasts express CD19 **(C)** and terminal deoxynucleotidyl transferase **(D)** in a patient with *BCR*::*ABL1*-positive CML diagnosed 8 years previously.

Differential Diagnosis

Chronic Phase

The differential diagnosis of CML-CP includes reactive leukocytosis, myeloid/lymphoid neoplasms with prominent eosinophilia, the MDS/MPNs (including CMML and aCML), and MPNS (including

CNL and the *BCR*::*ABL1*-negative MPNs). None of these neoplasms has a Ph chromosome or *BCR*::*ABL1* fusion gene but might be considered an alternative diagnosis if a case thought to be CML is determined to lack the genetic requirement. These myeloid neoplasms have been described in detail elsewhere in this chapter and in **Chapters 48** and **50**; the features that may overlap with CML, CP are briefly mentioned in **Table 47-2**.

Reactive Granulocytosis

Reactive granulocytosis and leukemoid reactions can usually be distinguished from CML by the clinical history or evidence of an underlying infection, inflammatory process, or nonmyeloid neoplasm that accounts for the abnormal peripheral blood findings, but careful examination of a blood smear is usually the most valuable tool in distinguishing reactive granulocytosis from CML. Basophilia and the "myelocyte bulge" characteristic of CML are absent in reactive granulocytosis, whereas toxic granulation or cytoplasmic vacuoles commonly observed in reactive neutrophilia are rarely found in CML. However, genetic studies to exclude CML should be performed in cases with persistent, unexplained neutrophilia, as CML—particularly those with the variant p230 transcript—may initially present with predominantly mature neutrophils and minimal granulocytic immaturity.[70,72]

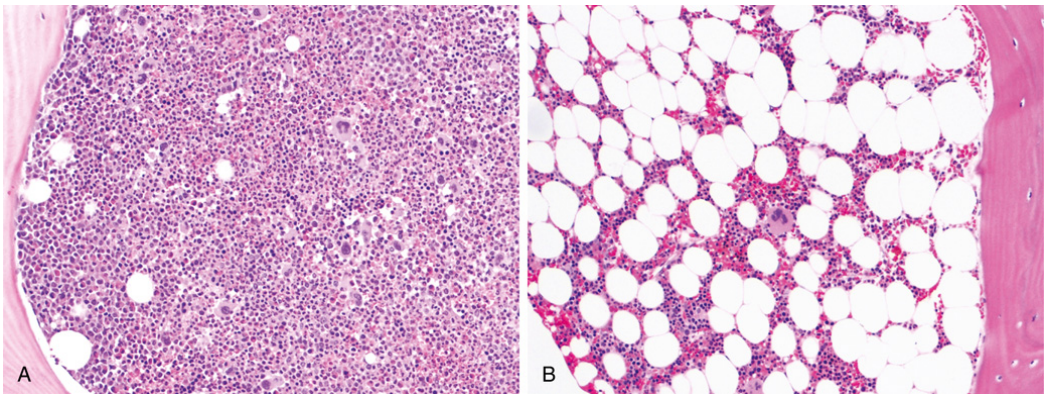

FIGURE 47-16 Initial bone marrow biopsy **(A)** of a patient with Ph-positive chronic myeloid leukemia and a repeated biopsy 12 months after the institution of imatinib therapy **(B)**, at which time a complete hematologic and cytogenetic remission had been achieved. Notice the small megakaryocytes in the initial marrow and the normal-sized megakaryocytes in the remission marrow.

Table 47-2

aCML, Atypical chronic myeloid leukemia; *CML,* chronic myeloid leukemia; *CMML,* chronic myelomonocytic leukemia; *CNL,* chronic neutrophilic leukemia.

Reactive and Neoplastic Disorders Associated With Eosinophilia

Most cases of eosinophilia are secondary to inflammatory diseases (including allergies, hypersensitivity conditions, and collagen vascular diseases), infections (particularly with tissue-invasive

parasites), or nonmyeloid neoplasms in which reactive or neoplastic T cells or other inflammatory cells secrete cytokines that promote eosinophil proliferation. However, a number of myeloid disorders are associated with persistent hypereosinophilia (≥1500 eosinophils/μL), in which the eosinophils belong to the neoplastic clone. These include the group of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions (M/LN-Eo); chronic eosinophilic leukemia, not otherwise specified; and CML.[1,102] The first two conditions are described in detail in **Chapter 50**, but some cases of CML have an absolute eosinophil count that exceeds 1500 eosinophils/μL and should be included in the differential diagnosis. In any case with unexplained hypereosinophilia, appropriate genetic studies, including *BCR*::*ABL1* analysis, should be performed without delay. Early diagnosis and treatment of hypereosinophilia is essential, as eosinophils release cationic proteins that may lead to extensive tissue damage, particularly in the cardiovascular, pulmonary, or central nervous systems.

Chronic Myelomonocytic Leukemia (CMML)

CMML is characterized by monocytosis in the blood (≥0.5 × 10^9/L and 10% or more monocytes), cytopenia, presence of clonality by cytogenetics or at least one myeloid neoplasm associated mutation, and less than 20% blasts in the blood or bone marrow.[1,103] There is no Ph chromosome or *BCR*::*ABL1* fusion gene. The "≥10% monocytes rule" for the diagnosis of CMML is helpful to distinguish CMML from CML. A patient with CML and a WBC count of 100 × 10^9/L with only 1% monocytes in the blood has an absolute monocyte count of 1000/μL, but rarely do CML patients have 10% or more

monocytes in the blood. On the other hand, CMML often has prominent granulocytic proliferation in the marrow and small, dysplastic megakaryocytes that may resemble the dwarf megakaryocytes characteristic of CML. In addition, splenomegaly is common in both disorders. Thus, confusion between CMML and CML is possible. Furthermore, the rare cases of CML that carry the BCR::ABL1 fusion protein p190 have monocytosis and closely mimic CMML. Therefore, the leukemic cells of any patient in whom the diagnosis of CMML is considered should be analyzed by routine karyotyping, FISH, or RT-PCR to exclude the possibility of CML.

Atypical CML (aCML)

Atypical CML is not an atypical form of CML.[1,103] Though aCML is characterized by leukocytosis with neutrophilia and immature circulating neutrophilic precursors, associated with a granulocytic proliferation in the marrow, there is no *BCR*::*ABL1* fusion gene, and in contrast to CML, the granulocytes in aCML are dysplastic, there is no significant basophilia or eosinophilia, and thrombocytopenia is common.

Chronic Neutrophilic Leukemia (CNL)

CNL is an MPN characterized by a proliferation of normal-appearing neutrophils lacking granulocytic dysplasia with only rare (<10%) circulating granulocytic precursors. CNL lacks a *BCR*::*ABL1* fusion gene but has a high prevalence of mutations in *CSF3R* that activate the receptor, leading to the proliferation of neutrophils. A subset of cases of CML can show marked neutrophilia; however, they are associated with a BCR::ABL1 fusion protein, often p230. A positive *BCR*::*ABL1* FISH result will help in identifying these rare cases.

Myeloid or Lymphoid Blast Phase

The differential diagnosis of CML-BP is not problematic if there is a history of preexisting CML; but occasional patients with CML initially present in BP, in which case it may be nearly impossible to distinguish between CML-BP and de novo Ph-positive ALL, Ph-positive mixed phenotype acute leukemia, or Ph-positive AML. If the blood or bone marrow shows blasts in a background of granulocytes with a left shift, myelocyte bulge, absolute basophilia, or dwarf megakaryocytes, the diagnosis of CML-BP is most likely. However, if these features are absent and blasts constitute the majority of cells in the blood and bone marrow, the diagnosis is sometimes more difficult. If a p190 transcript is present, the diagnosis of Ph-positive ALL de novo is strongly supported.[72] A breakpoint in the major *BCR* region does not resolve the issue, however, because a minority of cases of apparent Ph-positive ALL de novo demonstrate the p210 transcript. One detailed study that examined the morphology of cells harboring the *BCR*::*ABL1* fusion gene in cases of Ph^+ B-ALL in children reported that, in some cases, only the lymphoblasts harbored the fusion gene, whereas in others, the myeloid and lymphoblasts were *BCR*::*ABL1* positive. In the latter group, some patients had a CML-CP picture after therapy, suggesting the lineage of involvement may be more limited in Ph-positive ALL than in CML.[104] Whether de novo Ph-positive AML exists has been a controversial issue, but data suggest that such cases can be recognized by deletions within the TCR and IGH genes, usually accompanied by loss of *IKZF1* and *CDNK1A/B,* which will distinguish the de novo leukemia from CML in myeloid BP.[105,106]

Chronic Neutrophilic Leukemia (CNL)

Definition

CNL is a rare MPN characterized by sustained neutrophilia in the peripheral blood and a proliferation of neutrophilic granulocytes in the bone marrow that is shifted toward mature forms.[107] Hepatosplenomegaly is commonly present as a result of leukemic infiltration of the spleen and liver. Most patients with CNL have been shown to have point mutations in the proximal membrane region of *CSF3R* (exon 14), the gene encoding the CSF3R.[36] These mutations lead to constitutive activation of JAK/STAT signaling and are the drivers of the abnormal granulocytic proliferation. Detection of mutations of *CSF3R* is a valuable diagnostic tool to distinguish CNL from reactive leukocytosis, which it most closely resembles. There is no Ph chromosome or *BCR*::*ABL1* fusion gene; cases of marked neutrophilia associated with a BCR::ABL1 fusion protein, including p230, are categorized as CML, not CNL.[70,72] The diagnosis of "*CSF3R*-negative" CNL requires exclusion of reactive neutrophilia and other MPNs and MDS/MPNs.

Synonyms and Related Terms

None.

Diagnosis

The diagnosis of CNL may be problematic because of its rarity and the overlap of its morphologic findings with those of infection, inflammation, and other myeloid neoplasms.[108] Previous criteria for CNL were largely exclusionary to rule out leukemoid reactions, other MPNs, and neutrophilia as a result of abnormal cytokine release by

hematopoietic or non-hematopoietic neoplasms. Furthermore, nearly 30% of reported cases of CNL occurred in patients with a concomitant plasma cell neoplasm.[109,110] Most of these latter cases are thought to be reactive neutrophilia caused by release of G-CSF from the neoplastic plasma cells rather than CNL. Still, in a few cases of CNL with associated plasma cell abnormalities, the plasma cells were proven to be clonal; thus, the relation between CNL and plasma cell neoplasms may not be entirely settled.[109,111]

The ICC criteria for the diagnosis of CNL are outlined in **Box 47-4**. The ICC guidelines lowered the key diagnostic threshold for leukocytosis from ≥25 to ≥13 × 10^9/L in cases with *CSF3R* T618I or other activating *CSF3R* mutations. However, the proposed WHO 5th edition retained a leukocytosis threshold of ≥25 × 10^9/L for all cases.[2] The finding of *CSF3R* T6181 or other activating *CSF3R* mutations is a major step in establishing the neutrophil proliferation as clonal; however, these mutations are not present in all cases, and they have been reported in occasional cases of aCML and in AML that arises in a background of congenital neutropenia.[36,48,112] Therefore, correlation of clinical history, hematologic data, morphology of the blood and bone marrow, and cytogenetic and molecular genetic data is necessary to reach a final diagnosis of CNL.

Epidemiology

Epidemiologic data on CNL is limited as a result of challenges in making a diagnosis for reasons cited herein. The true incidence of CNL is unknown. Based on available data, the overall incidence is 0.1 cases/1,000,000 individuals in the United States.[113] Although CNL

usually affects adults in their 60s, it has been reported in all age groups with a slight male predominance.[108]

Clinical Findings

Many patients are asymptomatic when a complete blood count performed during a routine medical examination reveals leukocytosis, but others have symptoms of fatigue, bone pain, pruritus, easy bruising, or gout.[110,114] Bleeding diathesis can be seen in some patients. Splenomegaly is the most consistent physical finding and is present in about 36% of cases.[115] Hepatomegaly can also be present, but lymphadenopathy is uncommon.[116]

Morphologic Findings

Peripheral Blood

The WBC count is ≥13 × 10^9/L in patients with *CSF3R* T618I or other activating *CSF3R* mutations and ≥25 × 10^9/L in patients without *CSF3R* mutations (median, 50 × 10^9/L). Segmented neutrophils and bands account for 80% or more of the WBCs, whereas the sum of promyelocytes, myelocytes, and metamyelocytes is always less than 10% (**Fig. 47-17**). There is no significant granulocytic dysplasia, but toxic granulation or Döhle bodies may be seen. Myeloblasts are almost never observed in the blood at the time of diagnosis. Monocytes are less than 1 × 10^9/L, and there is no absolute basophilia or eosinophilia.[1,115] Mild to moderate anemia is common. The platelet count is usually normal; severe thrombocytopenia or thrombocytosis is rare. Findings of platelet function studies are reportedly abnormal in some cases, but most patients described in the literature have not been evaluated for platelet defects.

Box 47-4 Diagnostic Criteria* for Chronic Neutrophilic Leukemia (CNL) According to International Consensus Classification[1]

1. Peripheral blood white blood cell count ≥13 × 10^9/L[†]
   Segmented neutrophils plus banded neutrophils constitute ≥80% of the white blood cells.
      Neutrophil precursors (promyelocytes, myelocytes, and metamyelocytes) constitute <10% of the white blood cells
   No significant dysgranulopoiesis
   Circulating blasts only rarely observed[‡]
   Monocyte count <10% of all leukocytes
2. Hypercellular bone marrow with neutrophil granulocytes increased in percentage and absolute number, showing normal maturation
3. *CSF3R* T618I or another activating *CSF3R* mutation
   or
   Persistent neutrophilia (≥3 months), splenomegaly, and no identifiable cause of reactive neutrophilia including absence of a plasma cell neoplasm
   or
   If a plasma cell neoplasm is present, demonstration of clonality of myeloid cells by cytogenetic or molecular studies
4. Not meeting diagnostic criteria for *BCR*::*ABL1*-positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, primary myelofibrosis or of a

myeloid/lymphoid neoplasm with eosinophilia and tyrosine kinase gene fusions

---

* The diagnosis of CNL requires all four criteria.
‡ 10% to 19% blasts in peripheral blood or bone marrow represent CNL in accelerated phase; ≥20% blasts represents blast phase.
† At least 25 × 10^9/L in cases lacking *CSF3R* T618I or another activating *CSF3R* mutation.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Bone Marrow

The bone marrow biopsy is hypercellular for age and shows marked proliferation of neutrophils. The myeloid-to-erythroid ratio is often 20:1 or more (**Fig. 47-17**). The percentage of blasts and promyelocytes in the marrow is not increased at the time of diagnosis, but there is an increase in the percentage of myelocytes, metamyelocytes, bands, and segmented neutrophils.[108] The neutrophils in the bone marrow usually resemble those in the blood. It is important to note that there is no significant dysplasia in the granulocytes or any other myeloid lineage. Basophilia and eosinophilia are generally not observed. Erythroid precursors are usually reduced in percentage but are normoblastic. Megakaryocytes are also morphologically normal, but mild megakaryocytic proliferation has been reported in some cases. Mild increase of

reticulin fibrosis (MF-1) can be seen in a minority of cases.[115] Ten percent to 19% blasts in peripheral blood or bone marrow represent AP of disease, and ≥20% blasts represent BP of CNL. In view of the reported relation between neutrophilia and plasma cell abnormalities, careful attention should be given to the marrow plasma cells in all cases in which a diagnosis of CNL is contemplated. If abnormal or clonal plasma cells are present, clonality of the neutrophils should be demonstrated before a diagnosis of CNL is rendered.

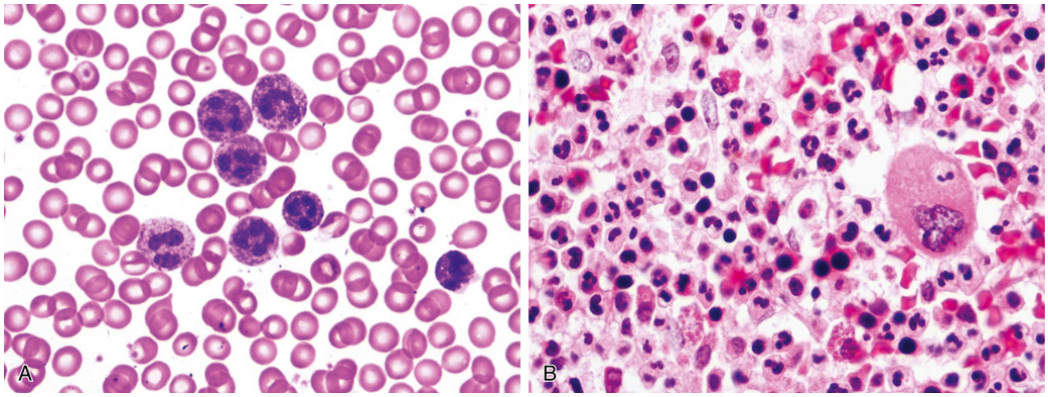

FIGURE 47-17 Chronic neutrophilic leukemia.A, Peripheral blood shows mainly segmented neutrophils with toxic granules. **B,** Biopsy shows a similar shift toward mature forms. No underlying disease could be found to explain the neutrophilia, and splenomegaly was present.

Extramedullary Tissues

Splenomegaly and hepatomegaly are caused by tissue infiltration by neutrophils. In the spleen, the infiltrate assumes a typical leukemic

pattern, with infiltration in the red pulp cords and sinuses, whereas in the liver, the sinuses or portal areas, or both, may be infiltrated.[117]

Genetics

Nearly 25% of patients who meet the current criteria for diagnosis of CNL have clonal cytogenetic abnormalities at diagnosis, and in another 10%, cytogenetic abnormalities appear during disease evolution.[116] None are specific for CNL, but their presence confirms the neoplastic nature of the neutrophilia. The most common abnormalities include +8, +9, +21, del(20q), and del(11q). There is no Ph chromosome or *BCR*::*ABL1* fusion gene and specifically no BCR::ABL1 p230 isoform, which is associated with CML with prominent neutrophilia or thrombocytosis but not with CNL.

The presence of driver mutations in the *CSF3R* is the diagnostic genetic signature of CNL and is seen in 80% of cases. The mutation most strongly associated with CNL is an activating point mutation in *CSF3R* T6181, located on chromosome 1p34.3, which encodes the transmembrane receptor CSF3R.[36,48-50] The absence of a *CSF3R* mutation does not exclude the possibility of CNL. Additional mutations can be seen in many cases, including *SETBP1, ASXL1, SRSF2,* and signaling mutations.[118] Occasional patients with CNL have been described with *JAK2* V617F and mutated *CALR*.[116]

Patients with CNL with *CSF3R* mutations were found to represent two phenotypically and prognostically distinct subsets.[119] The *CSF3R* T618I-mutated individuals clustered with adverse clinical and laboratory features, demonstrating more advanced age at diagnosis, higher white WBC counts, lower hemoglobin values and platelet counts at diagnosis, more frequently with abnormal

karyotype, and lower overall survival (OS) than patients harboring other *CSF3R* mutations.

Clinical Course

CNL follows a progressive disease course with a short overall survival of approximately 2 years.[108,113] Causes of death include intracranial hemorrhage, progressive disease, infections, and leukemic transformation.[108] Progression of CNL is often associated with increasing neutrophilia, worsening anemia, and thrombocytopenia. Transformation to AML has been reported to occur in 10% to 15% of cases.[110,117] Intracranial hemorrhage as a cause of death has been reported in a disproportionate number of patients. Although this may be a manifestation of an underlying coagulation or platelet abnormality, it may also be attributed to thrombocytopenia related to progressive disease or to therapy.[114,116]

Differential Diagnosis

The differential diagnosis of CNL includes reactive neutrophilia and other myeloid proliferations with a prominent neutrophil component. Reactive neutrophilia caused by infection and inflammation may be revealed by a thorough clinical history and additional laboratory studies, but inspection of the blood or bone marrow may not reveal any significant morphologic differences between reactive neutrophilia and CNL. Rouleaux formation of RBCs on the blood smear may suggest an underlying plasma cell lesion, in which case the blood should be examined for abnormal immunoglobulins and a bone marrow specimen searched for an abnormal plasma cell population. Epithelial tumors and sarcomas

may also secrete cytokines that stimulate neutrophil production. In the presence of either a plasma cell lesion or another underlying neoplasm, a diagnosis of CNL should not be made unless there is convincing evidence of clonality of the neutrophils, such as the presence of mutated *CSF3R*. Other disorders to consider in the differential diagnosis of CNL include CML associated with the p230 BCR::ABL1 isoform[72] and aCML. The distinguishing features of these neoplasms are listed in **Table 47-2**.

Classic *Bcr*::*Abl1*-Negative Myeloproliferative Neoplasms

This group of MPNs includes ET, PV, and PMF. They share a close association with *JAK2, CALR,* and *MPL* mutations, with *JAK2* mutation being the most prevalent in each one of these entities.

An accurate classification of MPNs in this category requires the following: (1) bone marrow aspirate smears and trephine biopsies collected at time of diagnosis, or within a short time frame thereafter, and in the absence of active therapy, especially with cytoreductive drugs; (2) adequate core biopsy specimens that are ≥1.5 cm in length, free of artifact, performed at a right angle to the cortical bone, and accompanied by properly spread particulate bone marrow aspirate smears; and (3) additional peripheral blood and bone marrow samples for cytogenetic and molecular studies, including *JAK2* (both exons 12 and 14), *CALR,* and *MPL* mutations.[120] A carefully processed specimen should allow accurate grading of fibrosis (3-grade scoring system) as shown in **Table 47-3** and assessment of age-adjusted hematopoietic cellularity, both of which are crucial diagnostic features.[121-123] **Figure 47-18**

demonstrates semiquantitative grading of bone marrow fibrosis. Assessment of bone marrow fibrosis must also include its quality (i.e., reticulin versus collagen).[124] A systematic approach integrating evaluation of bone marrow cellularity, relative proportions of the three lineages, spatial distribution/organization of the different hematopoietic cell lineages, and morphologic hallmarks of each lineage provides unique histologic patterns that have significant diagnostic value (**Table 47-4**).[125]

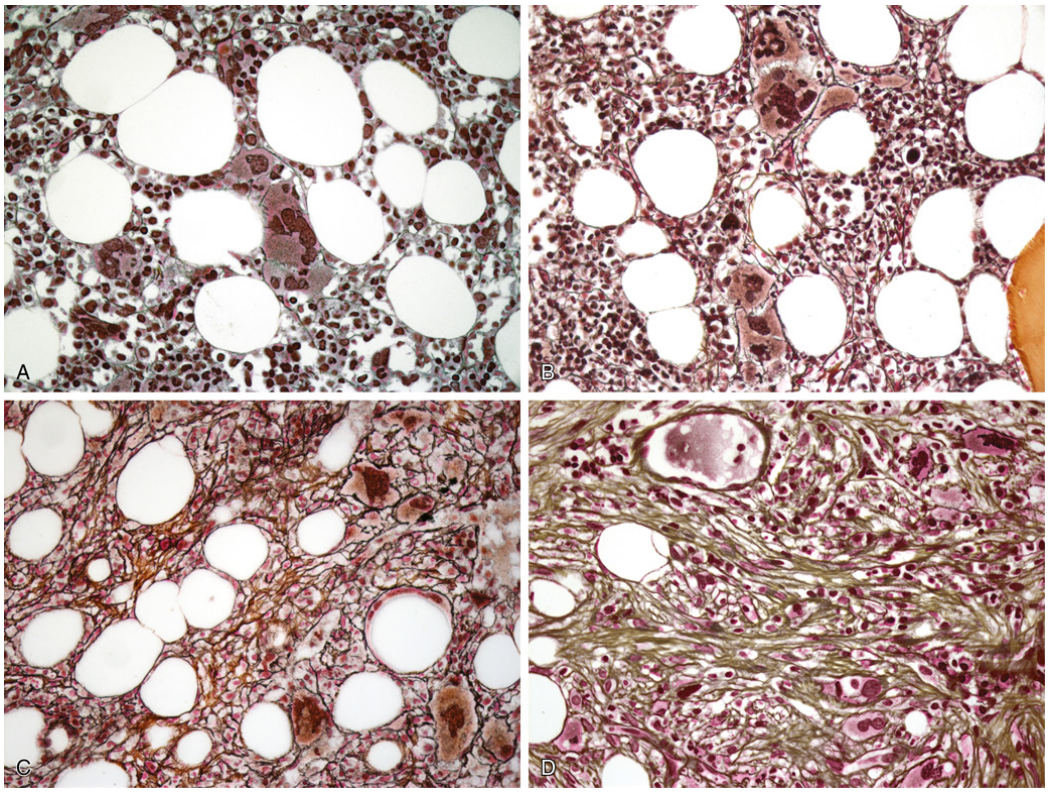

FIGURE 47-18 Semiquantitative grading of bone marrow fibrosis.A, Grade MF-0. **B,** Grade MF-1. **C,** Grade MF-2. **D,** Grade MF-3. See **Table 47-3** for a description of the grades.

Table 47-3

Semiquantitative Grading of Bone Marrow Fibrosis

Grade*	Description
MF-0	Scattered linear reticulin fibers with no intersections (crossovers), corresponding to normal bone marrow
MF-1	Loose network of reticulin with many intersections, especially in perivascular areas
MF-2†	Diffuse and dense increase in reticulin fibers with extensive intersections, occasionally with focal bundles of thick fibers mostly consistent with collagen or focal osteosclerosis
MF-3†	Diffuse and dense increase in reticulin with extensive intersections and coarse bundles of thick fibers consistent with collagen, usually associated with osteosclerosis

* Should be assessed only in hematopoietic areas. If the fibrosis pattern is heterogeneous, the final score is determined by the highest grade present in at least 30% of the marrow area.

† In grades MF-2 and MF-3, trichrome staining is recommended.

Data from Thiele J, Kvasnicka HM, Facchetti F, Franco V, van der Walt J, Orazi A. European consensus on grading bone marrow fibrosis and assessment of cellularity. *Haematologica*. 2005;90(8):1128-1132.

Essential Thrombocythemia (ET)

Definition

Essential thrombocythemia (ET) is a CMN characterized by sustained thrombocytosis of 450 × 10^9/L or more in the peripheral blood; increased numbers of large, mature megakaryocytes in the bone marrow; and episodes of thrombosis or hemorrhage.[126] The ICC diagnostic criteria for ET are listed in **Box 47-5**.

Synonyms and Related Terms

Idiopathic thrombocythaemia/thrombocytosis; essential hemorrhagicthrombocythaemia; idiopathic hemorrhagicthrombocythaemia; idiopathic thrombocythaemia; megakaryocytic myelosis; hemorrhagic thrombocythaemia; primary thrombocythaemia/thrombocytosis

Epidemiology

Incidence is estimated at 1.2 to 3.0 per 100,000 population per year[127] with a median age at diagnosis of 58 years and a slight female predominance.

Clinical Features

More than 50% of the patients are asymptomatic and discovered incidentally with thrombocytosis (by definition ≥450 × 10^9/L). It should be noted that reactive etiologies of thrombocytosis including infections, inflammation, recent acute bleeding, postsurgical state, splenectomy, and iron deficiency are more common than clonal thrombocytosis. In addition to ET, clonal thrombocytosis can be seen in PV, PMF, CML, and MDS/MPN with ring sideroblasts and

thrombocytosis (MDS/MPN-T-*SF3B1* and MDS/MPN-RS-T, NOS). Diagnosis of ET requires integration of clinical, morphologic, and laboratory features. Symptoms are more frequently associated with thrombosis, ranging from transient ischemic attacks involving small vessels to splanchnic vein thrombosis or hemorrhages, more frequently involving the gastrointestinal and respiratory tracts.[128,129] Splenomegaly is typically absent, but mild splenomegaly can be seen in 15% to 20% of cases; hepatomegaly is rare.

Morphology

Peripheral Blood

Thrombocytosis is the most striking abnormality noted on the hemogram and may range from 450 to more than 2000 × 10^9/L.[46,130] On microscopic examination, the platelets may show anisocytosis ranging from tiny to markedly enlarged forms. Atypical platelets including hypogranular, enlarged, or bizarrely shaped forms, can be seen but are uncommon (**Fig. 47-19**). The WBC count and leukocyte differential are usually normal; immature granulocytes are generally not present, and basophilia is minimal, if present at all.[126,130] The RBCs are usually normal unless there has been significant bleeding, in which case they may be hypochromic and microcytic; however, significant anisopoikilocytosis is uncommon, and teardrop-shaped RBCs are not observed. Leukoerythroblastosis is not present. Patients with mutated *CALR* reportedly have a lower Hb level but higher platelet counts than those with mutated *JAK2*.[46]

Bone Marrow

A bone marrow biopsy is essential to diagnose ET and to distinguish it from prefibrotic PMF, PV, other MPNs and myeloid neoplasms associated with thrombocytosis, and reactive thrombocytosis.[126,131,132]

Table 47-4

ET, Essential thrombocythemia; *PMF,* primary myelofibrosis; *pre-PMF,* early/prefibrotic primary myelofibrosis; *PV,* polycythemia vera.

Box 47-5 Diagnostic Criteria* for Essential Thrombocythemia (ET) According to International Consensus Classification[1]

Major Criteria

1. Platelet count ≥450 × 10^9/L
2. Bone marrow biopsy showing proliferation mainly of the megakaryocytic lineage, with increased numbers of enlarged, mature megakaryocytes with hyperlobulated staghorn-like nuclei, infrequently dense clusters[†]; no significant increase or left shift in neutrophil granulopoiesis or erythropoiesis; no relevant bone marrow fibrosis[‡]
3. Diagnostic criteria for *BCR*::*ABL1*-positive chronic myeloid leukemia, polycythemia vera, primary myelofibrosis or other myeloid neoplasms are not met
4. *JAK2, CALR,* or *MPL* mutation[§]

Minor Criteria

1. Presence of a clonal marker[||] or absence of evidence of reactive thrombocytosis[¶]

[||] Assessed by cytogenetics or sensitive next-generation sequencing techniques.

[*] The diagnosis of ET requires either all major criteria or the first three major criteria plus the minor criteria.

[‡] Very rarely a minor increase in reticulin fibers may occur at initial diagnosis (MF-1).

[†] Three or more megakaryocytes lying adjacent without other bone marrow cells in between; in most of these rare clusters <6 megakaryocytes may be observed; increase in large clusters (≥6 cells) accompanied by granulocytic proliferation is a morphologic hallmark of early/prefibrotic primary myelofibrosis.

[§] Highly sensitive assays for *JAK2* V617F (sensitivity level <1%) and *CALR* and *MPL* (sensitivity level 1% to 3%) are recommended; in negative cases, search for noncanonical *JAK2* and *MPL* mutations should be considered.

[¶] Reactive causes of thrombocytosis include a variety of underlying conditions like iron deficiency, chronic infection, chronic inflammatory disease, medication, neoplasia, or history of splenectomy.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute

leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

The bone marrow is normocellular for the patients' age, with only a few cases of mild hypercellularity (**Fig. 47-19**). Erythropoiesis, granulopoiesis, and the myeloid-to-erythroid ratio do not show significant abnormalities. The most striking abnormality in biopsy sections is an increase in the number and size of the megakaryocytes. They may occur in loose clusters but are more often dispersed throughout the bone marrow. There is a predominance of large-to-giant forms with abundant, mature cytoplasm and deeply lobulated or hyperlobulated nuclei that sometimes assume a staghorn appearance. Dense megakaryocyte clusters, defined as three or more megakaryocytes without other intervening bone marrow cells, are infrequent in ET and usually small (i.e., <6 megakaryocytes).[133] In these cases, differential diagnosis with prefibrotic PMF might be challenging, but lack of atypia of the megakaryocytes (increased nuclear-to-cytoplasmic ratio, irregular chromatin clumping, and bulbous appearance), lack of granulocytic proliferation, and lack of clinical features like increased lactate dehydrogenase (LDH) or splenomegaly are key to distinguishing these cases from prefibrotic PMF.

Myeloblasts are usually less than 5%, and a mild increase in reticulin fibers (MF-1) is rare, being present in less than 5% of patients at initial diagnosis.[125,134,135]

Bone marrow aspirate smears may not be as informative as marrow biopsy. The smears often show large megakaryocytes, frequently associated with large pools of platelets. Emperipolesis of bone marrow cells is sometimes seen; however, this is not specific

and can also be seen in megakaryocytes from normal or reactive bone marrow specimens.

Extramedullary Tissues

Splenic enlargement is uncommon at the time of diagnosis; if present, it may be largely because of pooling and sequestration of platelets. Extramedullary hematopoiesis is absent or minimal.

Genetics

Cytogenetics

The majority of cases with ET demonstrate a normal karyotype. According to published data on cytogenetically annotated patients with well-defined ET, 7% had abnormal karyotype, including loss of chromosome Y (2%) and abnormalities other than –Y (4.8%), the most frequent being sole 20q–.[136] The cytogenetic findings were associated with clinical and molecular genetic findings and prognosis. Abnormal karyotype, other than –Y, was associated with older age, higher leukocyte count, and arterial thrombosis history. Normal karyotype/–Y clustered with *ASXL1* mutations, and abnormal karyotype clustered with *TP53* mutations. The OS was significantly shorter in patients with abnormal karyotype or –Y than in those with normal karyotype (medians 12, 10, and 21 years, respectively).

Mutations

Driver mutations for *JAK2* V617F (50%–70%), *CALR* (20%–25%), and *MPL* (3%–8%) are seen in the majority of patients with ET; however, up to 10% of cases can be triple negative.[137,138] Except for PV, in which *CALR* or *MPL* mutations virtually do not occur, the type

of driver mutations are not helpful in differentiating ET from other MPNs. However, the type of mutations has functional consequences. *JAK2* V617F is associated with older age, higher hemoglobin level, leukocytosis, lower platelet count, and increased risk of thrombosis.[139-141] Mutant *CALR* (vs. *JAK2*) is associated with younger age, male sex, higher platelet count, lower hemoglobin level, lower leukocyte count, and lower incidence of thrombotic events, and type 2 *CALR* mutations (vs. type 1) are associated with higher platelet count.[141]

By next-generation sequencing (NGS) analysis in patients with confirmed ET, mutations other than *JAK2/CALR/MPL* can be seen in some patients, the most frequent being *TET2* and *ASXL1*.[142] Presence of high molecular risk mutations (e.g., *TP53, SF3B1, SRSF2, U2AF1*) have been shown to affect overall, myelofibrosis-free, and leukemia-free survival rates.[136] In particular, *TP53* mutations have been associated with leukemic transformation.[136]

Clinical Course

The natural history of ET is that of an indolent disorder punctuated by episodes of thrombosis or hemorrhage with long symptom-free intervals. Median survival in ET has been reported to range from approximately 11 to 35 years, with a median of 35 years for patients aged 40 or younger, 22 years for those aged 41 to 60 years, and 11 years for those aged >60 years.[135,137,143] Thrombotic and hemorrhagic complications represent two of the main causes of morbidity and mortality in patients with ET, and therefore, the main goal of therapy is to prevent this outcome.

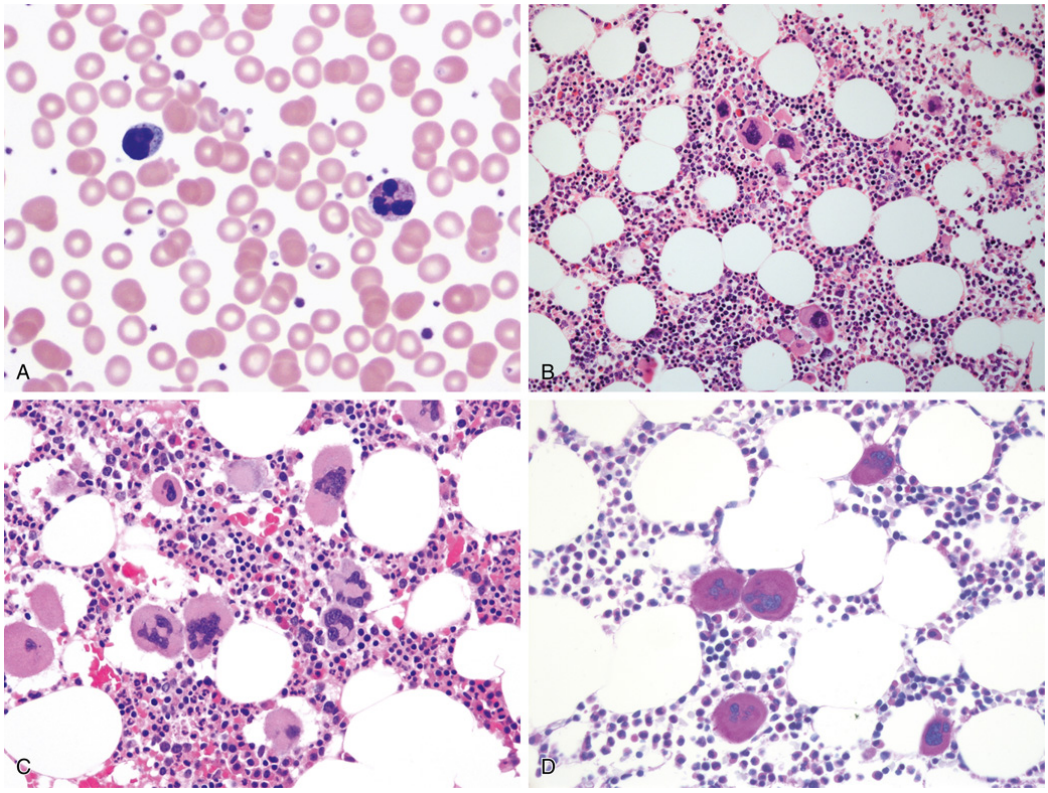

FIGURE 47-19 Essential thrombocythemia in a 42-year-old woman.A, Peripheral blood is largely unremarkable, except for thrombocytosis (800 × 10^9/L). **B, C,** Bone marrow biopsy exhibits normal cellularity but increased numbers of large megakaryocytes with hyperlobulated nuclei. **D,** Loose clustering of megakaryocytes can be observed.

Approximately 10% of ET cases can develop bone marrow fibrosis grade 2 to 3 associated with extramedullary hematopoiesis, so-called post-ET myelofibrosis. The diagnostic criteria for post-ET myelofibrosis are listed in **Box 47-6**. The cumulative probability of post-ET myelofibrosis is about 4% at 10 years and 9% at 15 years.

Risk factors for fibrotic transformation reportedly include older age, anemia, bone marrow hypercellularity, and reticulin fibrosis at diagnosis.[144] A large study of 1607 patients with ET from three independent centers showed a higher risk of fibrotic progression in patients with a *JAK2* V617F allele burden >35% and *CALR* type 1/1-like or *MPL* mutations.[145]

The risk of transformation to AP (10%–19% blasts) and BP (≥20% blasts) remains unpredictable, as the transformation may occur in young individuals even without detectable high-risk genomic profiles.[146] In other studies, reported risk factors for transformation to BP in ET included advanced age, extreme thrombocytosis, anemia, leukocytosis, and mutations involving *TP53* and *EZH2*.[147]

Box 47-6 Diagnostic Criteria* for Post-essential Thrombocythemia Myelofibrosis (post-ET MF)[1]

Required Criteria

1. Previous established diagnosis of ET
2. Bone marrow fibrosis of grade 2 or 3

Additional Criteria

1. Anemia (i.e., below the reference range given age, sex, and altitude considerations) and a >2 g/dL decrease from baseline hemoglobin concentration
2. Leukoerythroblastosis
3. Increase in palpable splenomegaly of >5 cm from baseline or the development of a newly palpable splenomegaly

4. Elevated lactate dehydrogenase (LDH) level above the reference range
5. Development of any 2 (or all 3) of the following constitutional symptoms: >10% weight loss in 6 months, night sweats, unexplained fever (>37.5 °C)

* The diagnosis of post-ET MF is established by all required criteria and at least two additional criteria.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Differential Diagnosis

Thrombocytosis is a common hematologic abnormality and is associated with a wide range of hematopoietic and non-hematopoietic neoplasms, inflammatory and autoimmune conditions, infections, recent bleeding, and iron deficiency (**Box 47-7**). Even the majority of cases with platelet counts of 1000 × 10^9/L or more are usually caused by a reactive megakaryocytic proliferation.[148] Of the MPNs that have marked thrombocytosis, ET is the disorder that most clinicians and pathologists associate with a markedly elevated platelet count; however, CML, PV, and prefibrotic PMF also demonstrate marked thrombocytosis, with platelet counts sometimes exceeding 1000 × 10^9/L, and each of them is more common than ET.

Reactive Thrombocytosis

There may be some clinical urgency to determine the reason for marked thrombocytosis because thrombohemorrhagic complications are more likely in thrombocytosis because of myeloid neoplasms than in reactive thrombocytosis. The clinical history, physical findings, examination of the peripheral blood smear, and a few ancillary laboratory studies are often sufficient to distinguish between reactive and neoplastic thrombocytosis. A history of chronic thrombocytosis, prior bleeding or thrombotic episodes, and the finding of splenomegaly favor MPN, whereas the lack of these plus any clinical or laboratory evidence of an underlying inflammatory disease, such as elevated C-reactive protein, or of a non-hematopoietic neoplasm favors reactive thrombocytosis. Nevertheless, if an underlying cause for the thrombocytosis is not readily apparent, studies for *JAK2* V617F, *CALR,* and *MPL* mutations and a *BCR*::*ABL1* fusion gene should be performed from the blood or bone marrow specimen, and the bone marrow should be examined for an MPN or any other hematopoietic or non-hematopoietic neoplasm that would explain the thrombocytosis (**Box 47-7**).

Box 47-7 Possible Causes of Thrombocytosis (Platelet Count ≥450 × 10^9/L)

Secondary (Reactive) Thrombocytosis

- Infection
- Inflammatory and autoimmune diseases
- Blood loss, hemorrhage

- Chronic iron deficiency
- Postsplenectomy
- Hyposplenism
- Trauma (particularly brain injury)
- Postsurgical procedures
- Neoplasms (nonhematopoietic and nonmyeloid)
- Bone marrow regeneration, rebound after chemotherapy

Myeloid Neoplasm Related

- Myeloproliferative neoplasms
- Chronic myeloid leukemia, *BCR*::*ABL1*-positive
- Polycythemia vera
- Primary myelofibrosis
- Essential thrombocythemia
- Acute myeloid leukemia or myelodysplastic syndrome with t(3;3)(q21.3;q26.2) or inv(3)(q21.3q26.2)
- Myelodysplastic syndrome with del(5q)
- Myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis (MDS/MPN-T-*SF3B1* and MDS/MPN-RS-T)

Other Myeloid Neoplasms Associated With Thrombocytosis

The most commonly encountered myeloid neoplasms associated with thrombocytosis other than ET include PV, prefibrotic early/primary myelofibrosis (pre-PMF), and CML. Each of these diseases has been characterized separately in this chapter; the

characteristic morphology that distinguishes ET from pre-PMF, which can sometimes be challenging, is summarized in **Table 47-5** and illustrated in **Fig. 47-20**. Some cases of CML, particularly those with the p230 oncoprotein, can initially display marked thrombocytosis and minimal leukocytosis; therefore, cytogenetic or molecular genetic studies should always be performed to exclude a *BCR*::*ABL1* fusion gene and CML as a cause of thrombocytosis.[72] Yet another diagnostic consideration is the possibility of MDS/MPN-T-*SF3B1* and MDS/MPN-RS-T, NOS. Both may resemble ET in that they are characterized by a platelet count of 450 × 10^9/L or greater and have a proliferation of megakaryocytes in the bone marrow that morphologically resemble those of an MPN. Furthermore, nearly half of cases carry the *JAK2* V617F mutation. However, MDS/MPN-T-*SF3B1* and MDS/MPN-RS-T, NOS demonstrate anemia and ineffective erythroid proliferation with dyserythropoiesis and ring sideroblasts, features not expected in an MPN. In the presence of an *SF3B1* mutation (≥10% variant allele frequency), an association with the *JAK2* V617F mutation is common, whereas mutations in *CALR* or *MPL* W515 are less frequent. Elevated platelet counts are uncommon in MDS and AML, but in some specific instances, the platelet count may be markedly elevated. MDS with del(5q) and MDS or AML with t(3;3)(q21.3;q26.2) or inv(3)(q21.3q26.2) are frequently associated with thrombocytosis. Cases of MDS with del(5q) are characterized by megakaryocytes that are usually smaller than normal and have hypolobulated nuclei, in contrast to the large and hyperlobulated nuclei of the megakaryocytes of ET. MDS and AML cases associated with t(3;3) or inv(3) are characterized by the proliferation of micromegakaryocytes.

FIGURE 47-20 Megakaryocytes in essential thrombocythemia (ET) and prefibrotic/early primary myelofibrosis (pre-PMF). Although ET and pre-PMF may have overlapping clinical and laboratory features, the megakaryocytes differ morphologically between the two disorders; however, megakaryocyte morphology is not the sole basis for diagnosis. The megakaryocytes illustrated in the *left* column of this figure (**A, C, E, G,** and **I**) are from cases of ET in which the majority (but not all) of the megakaryocytes have hyperlobulated nuclei and voluminous cytoplasm. In contrast, those illustrated in the *right* column (**B, D, F, H,** and **J**) are from cases of pre-PMF, in which the majority of megakaryocytes have an altered nuclear-to-cytoplasmic ratio, bulky, cloudlike nuclei, and an overall bizarre appearance.

Primary Myelofibrosis (PMF)

Myelofibrosis is an increase in the amount and density of the discontinuous, linear network of delicate reticulin fibers that provides the structural framework on which hematopoiesis normally occurs. This increase can vary from a focal, loose, yet nearly continuous network of reticulin fibers to dense, diffuse collagen fibrosis and osteosclerosis. Reticulin fibrosis and collagen fibrosis are non-specific, secondary responses to various injuries and

diseases that involve the bone marrow and are mediated by cytokines released from marrow stromal cells and hematopoietic cells, including megakaryocytes, T cells, and cells of the monocyte-macrophage lineages.[149,150] Reticulin fibrosis is commonly associated with infections and inflammatory conditions that involve the bone marrow, whereas overt collagen fibrosis more often accompanies neoplastic diseases, such as carcinoma and lymphoma, when they infiltrate the marrow.[149] However, nearly half of all cases of myelofibrosis are associated with myeloid neoplasms, the MPNs in particular. Although any MPN can demonstrate myelofibrosis, particularly during disease progression, PMF stands out as the MPN most commonly linked to this complication.

Definition

PMF is a clonal MPN characterized by a proliferation of abnormal megakaryocytes and granulocytes in the bone marrow, which in fully developed disease, i.e., overt PMF, is associated with significant fibrosis and extramedullary hematopoiesis.

Similar to the 2016 WHO classification, the ICC defines two subtypes of PMF: pre-PMF and overt fibrotic PMF. Several studies have defined the early/prefibrotic stage of PMF as different from ET and overt PMF because of its distinct clinical, morphologic, and molecular features.[137,151-153] Pre-PMF can present with isolated thrombocytosis and develop thrombohemorrhagic complications similar to ET. Cases of pre-PMF may progress to overt fibrotic PMF, and that blurs the distinction of the two “entities.” However, the rate of progression is variable, and not all patients with pre-PMF will necessarily develop an overt disease.[153]

Early/Prefibrotic Primary Myelofibrosis (Pre-PMF)

Pre-PMF was formally introduced in the WHO classification of tumors in 2001,[154] confirmed and revised in 2008,[155] and then further defined as its own entity in the WHO 2016 revision.[156] Pre-PMF is a clonal MPN characterized by megakaryocytic proliferation and atypia, without reticulin fibrosis grade >1, accompanied by increased age-adjusted bone marrow cellularity and granulocytic proliferation. The diagnostic criteria for pre-PMF as defined by ICC are listed in **Box 47-8**.

Synonyms and Related Terms

Early stage myelofibrosis

Epidemiology

There are no registry-based prevalence or incidence data available for pre-PMF, as many of these cases were previously diagnosed as ET. The incidence of pre-PMF may be grossly calculated by referring to results derived from reclassifications of bone marrow biopsies and corresponding clinical data to differentiate patients with "true" ET from those with pre-PMF, ranging between 14% and 18% after centralized evaluations at centers of excellence.[157-159]

Clinical Features

Approximately 30% to 40% of patients with pre-PMF are asymptomatic at diagnosis and present with an abnormal CBC, usually from anemia, leukocytosis, thrombocytosis, or more rarely, from splenomegaly. Thrombocytosis clinically mimicking ET is the most common and challenging presentation in pre-PMF. Less commonly, the diagnosis results from discovery of unexplained

leukoerythroblastosis or increased LDH level. Compared to those with overt PMF, patients with pre-PMF are younger, with higher hemoglobin, leukocyte, and platelet counts.[152] Symptomatic cases are characterized by constitutional symptoms (fatigue, weight loss, night sweats, dyspnea). The degree of splenomegaly varies depending on the stage and length of the disease, and splenomegaly is seen in approximately 45% of patients with pre-PMF.[152,160]

Box 47-8 Diagnostic Criteria* for Prefibrotic Early/Primary Myelofibrosis (pre-PMF) According to International Consensus Classification

Major Criteria

1. Bone marrow biopsy showing megakaryocytic proliferation and atypia,† bone marrow fibrosis grade <2, increased age-adjusted bone marrow cellularity, granulocytic proliferation, and (often) decreased erythropoiesis
2. *JAK2, CALR,* or *MPL* mutation‡

   or

   presence of another clonal marker§

   or

   absence of reactive bone marrow reticulin fibrosis¶
3. Diagnostic criteria for *BCR*::*ABL1*-positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, myelodysplastic syndromes, or other myeloid neoplasms are not met

Minor Criteria

1. Anemia not attributed to a comorbid condition
2. Leukocytosis ≥11 × 10^9/L
3. Palpable splenomegaly
4. Lactate dehydrogenase level above the reference range

---

* The diagnosis of pre-PMF requires all three major criteria and at least one minor criterion confirmed in two consecutive determinations.

‡ Highly sensitive assays for *JAK2* V617F (sensitivity level <1%) and *CALR* and *MPL* (sensitivity level 1% to 3%) are recommended; in negative cases, search for noncanonical *JAK2* and *MPL* mutations should be considered.

† Morphology of megakaryocytes in pre-PMF demonstrates a high degree of megakaryocytic atypia including small to giant megakaryocytes with a prevalence of severe maturation defects (cloud-like, hypolobulated, and hyperchromatic nuclei) and presence of abnormal large dense clusters (mostly >6 megakaryocytes lying strictly adjacent).

§ Assessed by cytogenetics or sensitive next-generation sequencing techniques; detection of mutations associated with myeloid neoplasms (e.g., *ASXL1, EZH2, IDH1, IDH2, SF3B1, SRSF2,* and *TET2* mutations) supports the clonal nature of the disease.

¶ Minimal reticulin fibrosis (MF-1) secondary to infection, autoimmune disorder or other chronic inflammatory conditions, hairy cell leukemia or another lymphoid

neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Morphology

Peripheral Blood

Pre-PMF is typically characterized by borderline anemia, mild leukocytosis, and moderate to marked thrombocytosis (mean platelet count, 962 × 10^9/L; range, 104–3215 × 10^9/L).[161,162] In the peripheral blood, the most striking finding is often the marked increase in platelets (**Fig. 47-21**). Mild neutrophilia with a left shift may be seen, but myeloblasts, nucleated RBCs, and teardrop-shaped RBCs are uncommon.

Bone Marrow

The bone marrow is characteristically hypercellular for the patient's age with a granulocytic proliferation and an increased myeloid-to-erythroid ratio. Megakaryocytes are also increased in number and often form dense clusters. They show pleomorphic features in terms of their size, shape, and nuclear features. Nuclear atypia (increased nuclear-to-cytoplasmic ratio, abnormal chromatin clumping, and bulbous nuclei) is usually pronounced (**Fig. 47-22**). By definition, reticulin fibrosis is absent (MF-0) or mild (MF-1). Considering dense clusters of megakaryocytes can also rarely be found in ET, diagnosis of pre-PMF and the differential diagnosis with ET should be based

on the evaluation of the complete histologic pattern, including the overall cellularity, myeloid-to-erythroid ratio, morphology of megakaryocytes, and size of their clusters, in conjunction with clinical data.

Extramedullary Tissues

Extramedullary hematopoiesis in the spleen is minimal, if any.

Genetic Findings

In pre-PMF, abnormal cytogenetics were found in about 18% of cases and unfavorable karyotypes (complex karyotype or single or two abnormalities, including +8, −7/7q−, i[17q], −5/5q−, 12p−, inv[3], or 11q23 rearrangement) in 4% to 8% of cases. Incidence of *JAK2* V617F mutations in pre-PMF is very similar to that in ET, ranging from 52% to 67% and 54% to 66%, respectively.[137,152]

In a large study comparing pre-PMF and overt-PMF, the three driver mutations (*JAK2* V617F, *MPL*W515x, and *CALR*) were similarly distributed in the two cohorts. *JAK2* V617F mutation was found in 67.2% of pre-PMF cases and in 58.2% of overt PMF cases; *CALR* type 1 and type 2 were found in 12.2% and 5.8% and 17.8% and 4.4%, respectively. Patients with *MPL* W515x mutation accounted for 4.7% and 6.0% in the two cohorts, respectively. The proportions of patients with triple-negative PMF, a prognostically negative condition, were similar: 10.1% and 13.6% in pre-PMF and overt PMF, respectively. On the contrary, the high mutation risk (HMR) category (any mutations in *ASXL1, SRSF2, IDH1, IDH2,* or *EZH2*) was less common in pre-PMF than in overt PMF.[152]

Clinical Course

Median survival in pre-PMF has been calculated to range between 11 to 17 years, contrasting to only 7 years in overt PMF. Grade 1 reticulin fibrosis and anemia at initial diagnosis have been identified as risk factors for progression from pre-PMF to overt PMF. In the largest study of well-diagnosed pre-PMF cases, the rate of progression to overt PMF at 10 years was 12.3%.[144] Variables associated with BP evolution include age >65 years, leukocytosis (WBC >15 × 10^9/L), an LDH ratio >1.5 times the normal institutional value, and cytogenetic abnormalities.[163] Thrombohemorrhagic complications occur in pre-PMF. Though the risk of arterial and venous thrombosis is similar to that in ET, major hemorrhages during follow-up are more common in pre-PMF.[127,128,143,164]

Differential Diagnosis

In a significant subset of patients with pre-PMF, the peripheral blood shows marked thrombocytosis, and the differential diagnosis includes other MPNs that present with increased platelet counts. These include CML, PV, ET, MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-T-*SF3B1* and MDS/MPN-RS-T, NOS), and a variety of nonmyeloid neoplasms and inflammatory conditions that provoke thrombocytosis through the release of inflammatory cytokines.

The lack of *BCR*::*ABL1* gene fusion excludes CML. In addition, in CML, the megakaryocytes can be increased; however, they are small, with hypolobated nuclei, and lack the nuclear atypia seen in pre-PMF.

In contrast to the tightly clustered, highly atypical megakaryocytes of pre-PMF found in a background of mainly neutrophils, the

megakaryocytes in PV are usually more dispersed in the bone marrow, have variable sizes but lack nuclear atypia, and are found in a background of mainly erythroid precursors.

In ET, the marrow is normocellular to mildly hypocellular for age and lacks granulocytic hyperplasia that is characteristic of pre-PMF. The megakaryocytes in ET are usually enlarged with deeply lobulated ("staghorn") nuclei, but they are not tightly clustered in most cases. Clinical features of increased LDH or splenomegaly are uncommon in ET. **Table 47-5** summarizes the salient clinical and morphologic differences between ET and pre-PMF.

Overt Primary Myelofibrosis

Overt primary myelofibrosis is a clonal MPN characterized by a proliferation of abnormal megakaryocytes and granulocytes in the bone marrow, with significant fibrosis and often extramedullary hematopoiesis. Approximately 10% to 15% of cases of overt PMF represent progression from pre-PMF.[144] About 50% of overt PMF cases are associated with the *JAK2* V617F mutation, 30% with mutated *CALR,* and 5% to 10% with mutated *MPL*. In the remaining 10% to 15% of cases, the driver mutation is not yet known; such cases are referred to as triple-negative PMF.[34,35,165] The diagnostic criteria of overt PMF are listed in **Box 47-9**.

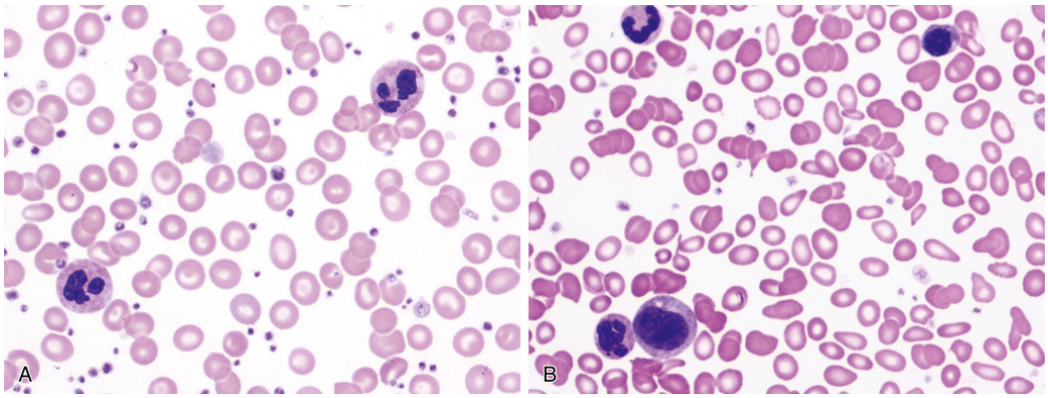

FIGURE 47-21 Blood smears from prefibrotic/early and fibrotic stages of primary myelofibrosis.A, This smear from the prefibrotic/early stage shows neutrophilia and thrombocytosis but minimal red cell changes (corresponding bone marrow is shown in **Fig. 47-23**). **B,** This smear from the fibrotic stage shows leukoerythroblastosis with marked red cell abnormalities, including many teardrop forms (corresponding bone marrow is shown in **Fig. 47-24**).

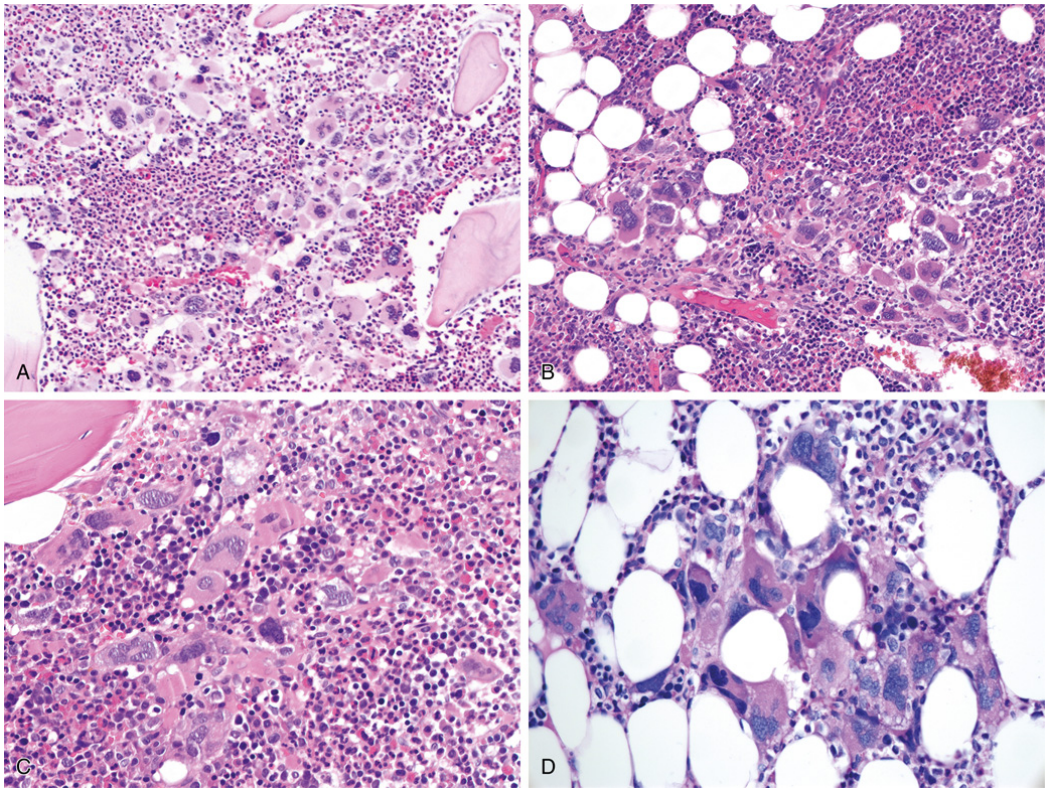

FIGURE 47-22 Prefibrotic primary myelofibrosis.A, B, Note the clusters of abnormal megakaryocytes in a background of neutrophils. This patient's peripheral blood is illustrated in **(A)**. **C, D,** Dense clusters of often more than six atypical megakaryocytes are a common finding.

Box 47-9 Diagnostic Criteria* for Primary Myelofibrosis (Overt Fibrotic Stage PMF) According to International Consensus Classification

Major Criteria

1. Bone marrow biopsy showing megakaryocytic proliferation and atypia,[†] accompanied by reticulin and/or collagen fibrosis grades 2 or 3
2. *JAK2, CALR,* or *MPL* mutation[‡]

   or

   presence of another clonal marker[§]

   or

   absence of reactive bone marrow reticulin fibrosis[||]
3. Diagnostic criteria for *BCR*::*ABL1*-positive chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, myelodysplastic syndromes, or other myeloid neoplasms[¶] are not met

Minor Criteria

1. Anemia not attributed to a comorbid condition
2. Leukocytosis ≥11 × 10^9/L
3. Palpable splenomegaly
4. Lactate dehydrogenase level above the reference range
5. Leukoerythroblastosis

[||] Reticulin fibrosis secondary to infection, autoimmune disorder or other chronic inflammatory conditions, hairy cell leukemia or another lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies.

[*] The diagnosis of PMF requires all three major criteria and at least one minor criterion confirmed in two consecutive determinations.

‡ Highly sensitive assays for *JAK2* V617F (sensitivity level <1%) and *CALR* and *MPL* (sensitivity level 1% to 3%) are recommended; in negative cases, search for noncanonical *JAK2* and *MPL* mutations should be considered.

† Morphology of megakaryocytes in PMF demonstrates a high degree of megakaryocytic atypia including small to giant megakaryocytes with a prevalence of severe maturation defects (cloud-like, hypolobulated, and hyperchromatic nuclei) and presence of abnormal large dense clusters (mostly >6 megakaryocytes lying strictly adjacent).

§ Assessed by cytogenetics or sensitive next-generation sequencing techniques; detection of mutations associated with myeloid neoplasms (e.g., *ASXL1, EZH2, IDH1, IDH2, SF3B1, SRSF2,* and *TET2* mutations) supports the clonal nature of the disease.

¶ Monocytosis can be present at diagnosis or develop during the course of PMF; in these cases, a history of myeloproliferative neoplasm (MPN) excludes chronic myelomonocytic leukemia (CMML). Furthermore, a higher variant allelic frequency for MPN-associated driver mutations supports the diagnosis of PMF with monocytosis rather than CMML. In contrast, multihit *TET2* mutations, often in combination with mutated *ASXL1* and *SRSF2,* are very common in CMML.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Although granulocytes and megakaryocytes are the major proliferative cells, all myeloid lineages, B lymphocytes, and some T lymphocytes are derived from the neoplastic clone.[166] In contrast, the fibroblasts are not clonal. Rather, the myelofibrosis and osteosclerosis are secondary changes caused by the abnormal release of growth factors and fibrogenic cytokines, including, among others, platelet-derived growth factor and transforming growth factor β, which are synthesized, packaged, and released from abnormal megakaryocytes and platelets.[149,167,168] There is also prominent angiogenesis in the bone marrow and spleen as a result of increased serum levels of vascular endothelial growth factor. Other cytokines that are increased in overt PMF include macrophage inflammatory protein 1β, tissue inhibitor of metalloproteinase, insulin-like growth binding factor 2, and tumor necrosis factor alpha. Therefore, the morphologic and some of the clinical features are related not only to the hematologic effects of the neoplastic cells in the marrow but also to the release of multiple inflammatory cytokines.[168-170]

Epidemiology

Incidence of overt PMF accounts for 0.5 to 1.5 cases per 100,000 population per year. Both sexes are equally affected. The median age at diagnosis is in the 7th decade; less than 10% are younger than 40 years. Although PMF has been reported in children, it is exceedingly

rare, and every effort should be made to exclude other diseases that might mimic PMF in a child.[171,172]

Clinical Features

Clinical manifestations in overt PMF include severe anemia, marked hepatosplenomegaly, constitutional symptoms (e.g., fatigue, night sweats, fever), cachexia, bone pain, splenic infarct, pruritus, thrombosis, and bleeding.[169] Ineffective erythropoiesis and hepatosplenic EMH are the main causes of anemia and organomegaly, respectively. Splenomegaly, caused by EMH, can be massive and may lead to early satiety, abdominal discomfort, or acute abdominal pain caused by splenic infarct.[169] Aberrant cytokine production by clonal cells and host immune reaction are thought to contribute to PMF-associated bone marrow stromal changes, ineffective erythropoiesis, EMH, cachexia, and constitutional symptoms. Causes of death in overt PMF include leukemic progression that occurs in approximately 20% of patients and comorbid conditions, including cardiovascular events and consequences of cytopenias such as infection or bleeding.[173]

Morphology

Peripheral Blood

Leukoerythroblastosis with numerous teardrop-shaped RBCs is common (**Fig. 47-21B**). Although mild leukocytosis is common in the fibrotic stage, severe leukopenia may occur, as bone marrow failure becomes more prominent as a result of increasing fibrosis. Circulating megakaryocytic nuclei and fragments are frequently observed at this time. Blasts can be seen on the peripheral blood

smear during the fibrotic stage and occasionally account for 5% or more of the WBCs. However, when this is the case, the patient should be carefully monitored for further evidence of progression to AP or BP. Absolute monocyte counts above 1×10^9/L have also been reported to indicate disease acceleration. Blast percentages of 10% to 19% in the peripheral blood indicate there is progression to AP, and 20% or more blasts is sufficient for the diagnosis of blast transformation.[169,174]

Bone Marrow

A bone marrow biopsy is essential for the diagnosis of overt PMF. An adequate, well-processed biopsy allows assessment of cellularity, the relative number of cells in the various myeloid lineages and their degree of maturation, megakaryocyte morphology, and the amount and grade of fibrosis—all of which are critical for establishing the diagnosis and following disease progression. The stain for reticulin fibers should be performed with a standard, uniform protocol to avoid technical variation, and the reticulin fiber content should be evaluated with a reproducible, semiquantitative grading system (**Table 47-3**; **Fig. 47-18**).[175] An immunohistochemical stain for CD34 is helpful to highlight blasts, particularly in cases with a dry tap. If a bone marrow aspirate is obtained, it may provide helpful information about maturation of the neoplastic cells.

In most cases, the bone marrow is hypercellular for age and shows an increased number of neutrophils and atypical megakaryocytes. Erythropoiesis is usually reduced. The megakaryocytes are markedly abnormal in both their topography and cytology and are the key that distinguishes PMF from the other MPNs. Megakaryocytes in PMF

are morphologically more atypical than in any other MPN. The megakaryocytes are often present in dense clusters defined as ≥3 megakaryocytes present back-to-back without any cells in between; however, the majority of patients show large clusters with more than six atypical megakaryocytes. The megakaryocytes vary from small to large with an abnormal nuclear-to-cytoplasmic ratio and disorganized, plump, cloud-like, or balloon-like nuclear lobulation. The nuclei are often hyperchromatic, but numerous bare megakaryocytic nuclei may be seen as well. There is an increase in reticulin fibers, at least grade 2, and a trichrome stain typically shows deposition of collagen (MF-2 or MF-3) (**Fig. 47-23**).

With disease progression, the marrow cellularity decreases, and at times, the marrow can appear nearly depleted of normal hematopoiesis. Reticulin or even overt collagen fibrosis of the marrow becomes more obvious. Islands of hematopoiesis are separated by regions of loose connective tissue or by fat or dense fibrosis. Dilation of marrow sinuses is usually prominent, and the sinuses may contain megakaryocytes and other immature hematopoietic cells, a feature which is particularly prominent in patients in the advanced stage. New bone formation and osteosclerosis are usually present at this time.[174]

The finding of 10% to 19% blasts in the blood or bone marrow is indicative of PMF in an accelerated disease stage, whereas 20% or more blasts is evidence of transformation to BP.[174]

Extramedullary Tissues

Many of the morphologic abnormalities noted in the peripheral blood in the fibrotic stage, such as teardrop-shaped RBCs and

leukoerythroblastosis, are caused by the abnormal release of cells from sites of EMH, particularly the spleen and liver, although almost any organ, including the kidney, breast, adrenal gland, lymph node, dura mater, and other soft tissues, can be involved (**Fig. 47-24**). The EMH seen in various tissues in overt PMF is composed of neoplastic cells, likely derived from hematopoietic stem cells, and precursor cells from the bone marrow.[176] The structure of the marrow sinuses is distorted and compromised by surrounding reticulin fibrosis, which allows immature, proliferative bone marrow cells to gain access to the marrow sinuses and hence to the circulation. CD34-positive cells are markedly increased in the blood of patients with PMF compared with those of patients with other MPNs and normal controls, and an increase in CD34-positive cells can also be demonstrated in the spleen.[177] Morphologically, the EMH in the spleen can be present as nodules or as diffuse involvement of the red pulp. A diffuse granulocytic predominance seems to portend a worse prognosis.[178] In some cases, the spleen may be the site of extramedullary leukemic transformation.

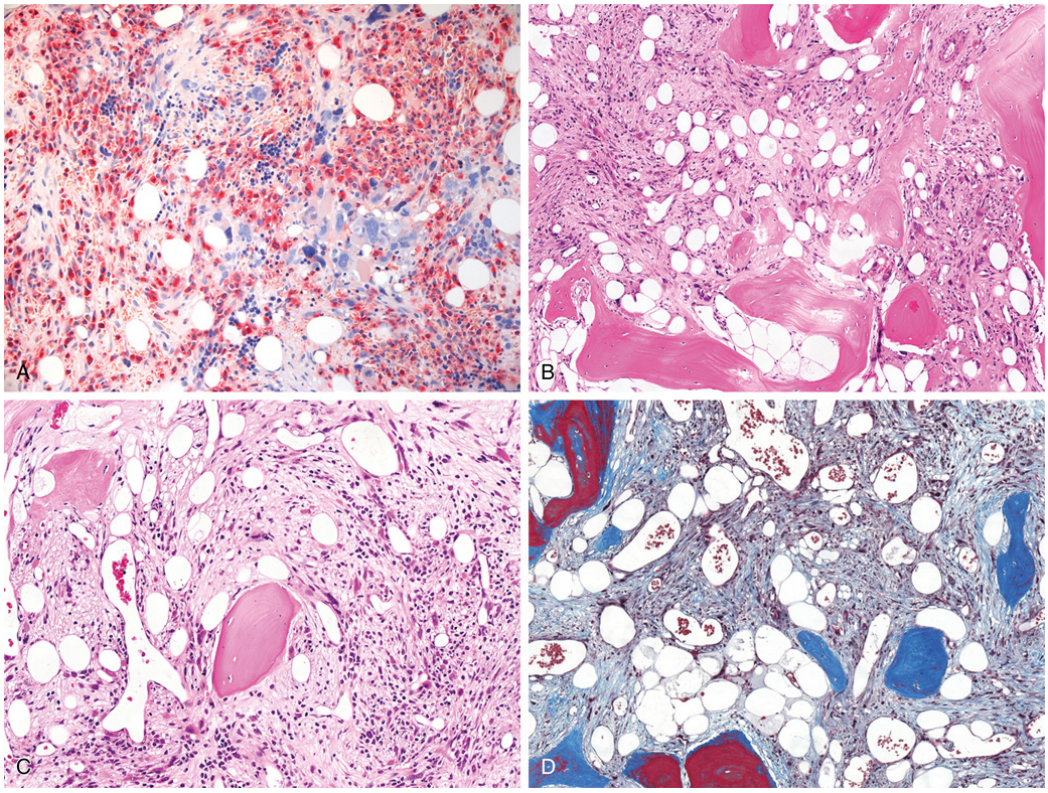

FIGURE 47-23 Overt primary myelofibrosis.A, Bone marrow shows numerous dense clusters of atypical megakaryocytes (MF-2). This patient's peripheral blood is illustrated in **Figure 47-22B**. **B,** In more advanced disease stages (MF-3), osteosclerosis can be seen. **C,** Overall cellularity can be significantly reduced in overt fibrotic cases because of the gross accumulation of collagen fibers, as illustrated in **(D)** (Masson's trichrome stain).

Genetics

No specific genetic marker has been identified for overt PMF. Approximately 50% to 60% of patients have *JAK2* V617F, 25% to 30% have mutated *CALR,* and 5% to 10% carry mutations of *MPL;* these genetic abnormalities are mutually exclusive.[169,179,180] The remaining cases carry none of the currently known MPN driver mutations and are referred to as triple negative. The driver mutations result in constitutive activation of Janus kinase–signal transducers and activators of transcription (JAK-STAT) target genes.[174] *CALR* mutations occur more often in younger patients with a higher platelet count and, in the case of type 1 *CALR* mutations, a more favorable prognosis, whereas the patients with triple-negative PMF have inferior survival.[181,182] Mutations other than *JAK2/CALR/MPL* that include *ASXL1, SRSF2, IDH1/IDH2, EZH2, SF3B1,* and *TET2,* among others, are also seen in patients with PMF and have been reported in up to 80% of PMF patients in one study.[180] Identification of these mutations is useful in establishing clonality in triple-negative PMF cases. These additional mutations likely affect various phenotypic features of PMF, including prognosis. In addition, some studies have demonstrated the presence of somatic noncanonical variants or germline *MPL* or *JAK2* variants in some patients with triple-negative PMF.[183,184]

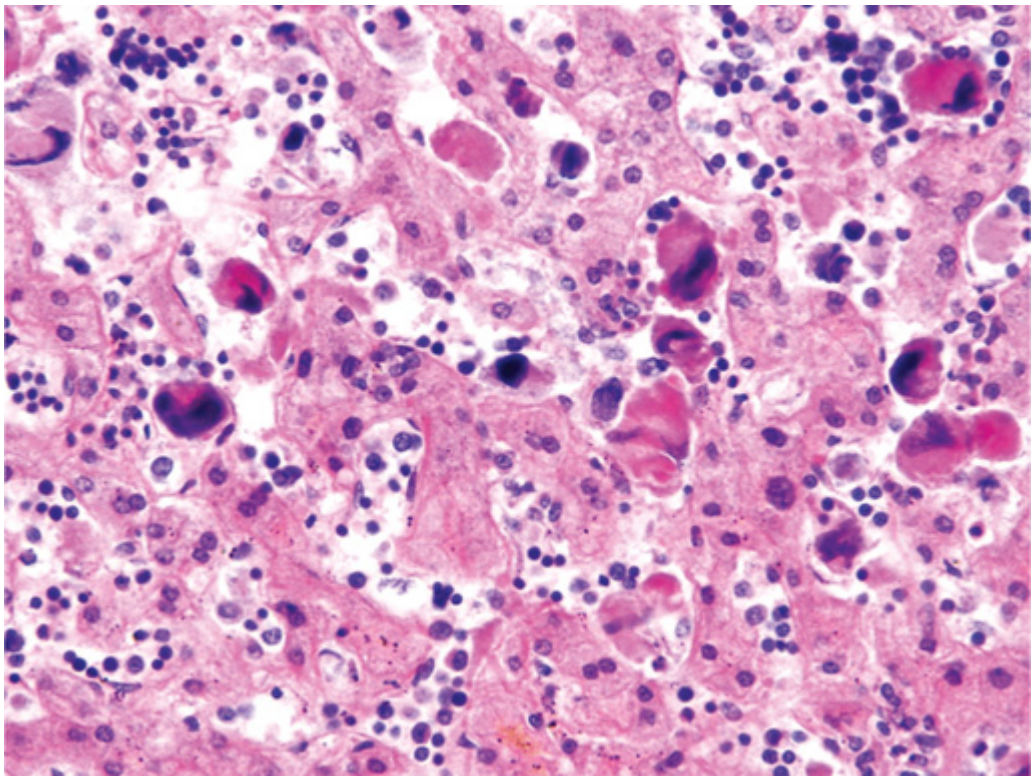

FIGURE 47-24 Extramedullary hematopoiesis in the liver of a patient with primary myelofibrosis. Note that the sinuses are filled with hematopoietic cells, and megakaryocytes are particularly prominent.

Karyotypic abnormalities are present in 40% to 50% of patients with overt PMF. The most frequent abnormalities include del(20q), del(13q), +8, +9, and abnormalities of 1q. Complex karyotypes are found in about 15% of cases.[185] More than 90% of patients who experience a leukemic transformation have cytogenetic abnormalities that are often complex and involve abnormalities of chromosomes 5 and 7.

Knowledge of cytogenetics and somatic mutations not only facilitates a diagnosis of MPN but is also used as a prognostic factor.

Clinical Course

The clinical course of overt PMF includes progressive anemia, often requiring RBC transfusions, marked hepatosplenomegaly, profound constitutional symptoms, and cachexia. The natural evolution of PMF is gradual progression to a markedly fibrotic, often osteosclerotic, bone marrow with cellular depletion, dilated marrow sinuses with intrasinusoidal hematopoiesis composed mainly of abnormal megakaryocytes, osteosclerosis, and eventually, bone marrow failure. The increase in spleen size from EMH contributes to the worsening cytopenias because of splenic sequestration and also leads to portal hypertension and abdominal pain. Myeloid blast transformation occurs in about 5% to 20% of cases at a median of 3 years after the diagnosis of the fibrotic stage of PMF.[169]

The median survival is about 7 years for overt PMF. The survival of patients with PMF depends on the stage in which the diagnosis is made and the number of parameters that are present that have been determined to adversely affect prognosis. Prognostic assessment tools for PMF have evolved over the years. The International Prognostic Scoring System (IPSS) developed in 2009 included clinical and laboratory variables at diagnosis. The Dynamic International Prognostic Scoring System (DIPSS) uses the same clinical and laboratory variables obtained at any time point of disease course. The more recent models incorporate cytogenetic and molecular genetic findings for risk stratification and are used to inform decisions to select patients with PMF for allogeneic transplant.[160,186-188] The genetically inspired prognostic scoring system (GIPSS) is based exclusively on mutations and karyotype, and MIPSS70+ version 2.0 (mutation-enhanced and karyotype-enhanced

international prognostic scoring system) uses both genetic and clinical risk factors.[189] Mutations comprising the high mutation risk category for prognosis or leukemia-free survival include those of *ASXL1, SRSF2*, *IDH1, IDH2,* and *EZH2*. Both the type of mutation and number of mutations have been shown to affect prognosis.[180,190]

Similar to somatic mutations, cytogenetic abnormalities are used for prognostic assessment. The revised cytogenetic risk categories include a three-tiered risk model: "very high risk (VHR)"—single/multiple abnormalities of −7, i(17q), inv(3)/3q21, 12p−/12p11.2, 11q−/11q23, or other autosomal trisomies not including +8 or +9 (e.g., +21, +19); "favorable"—normal karyotype or sole abnormalities of 13q−, +9, 20q−, chromosome 1 translocation/duplication, or sex chromosome abnormality including −Y; "unfavorable"—all other abnormalities.[191] The 5-year survival rates independent of clinically derived prognostic systems, driver and "additional" mutations, range from 8% for VHR to 45% for "favorable" karyotype.

Differential Diagnosis

The differential diagnosis of overt PMF includes post-PV and post-ET myelofibrosis. Whether this distinction can be made with confidence is controversial; some authors have noted that the megakaryocytes in the fibrotic stages of PV, PMF, and ET retain similar morphology as in the proliferative stages of these diseases, but others have not been able to make such a distinction.[192,193] The differentiation of other myeloid neoplasms, metastatic tumors, and

even inflammatory diseases associated with thrombocytosis can be challenging.

Other myeloid neoplasms to consider in the differential diagnosis of overt PMF include acute panmyelosis with myelofibrosis (APMF) and myelodysplastic syndrome with fibrosis (MDS-F). **Table 47-6** shows a comparison of salient features in PMF, MDS-F, and APMF.

APMF is a subtype of AML with myelofibrosis generally associated with multilineage dysplasia, small dysplastic megakaryocytes, and 20% or more blasts in the blood or bone marrow.[194] The blasts typically express CD34.[194] Patients with APMF usually present with acute onset of severe constitutional symptoms, pancytopenia, no splenomegaly, and increased circulating blasts. Although genetic data is available in only a small number of patients with APMF, no *JAK2* V617F, *MPL,* or *CALR* mutations have been detected.[195]

MDS-F, though not a distinct entity in the ICC, is recognized as a distinct subtype in the proposed WHO 5th edition.[2] It is characterized by peripheral cytopenia, hypercellular marrow with increased dysplastic megakaryocytes and often increased blasts, and significant marrow fibrosis (MF-2 or MF-3). Though megakaryocytic hyperplasia and fibrosis are similar to overt PMF, in MDS-F, the megakaryocytes are small with hypolobated nuclei and often include micromegakaryocytes (**Fig. 47-25**). Tight clusters of megakaryocytes are uncommon, and nuclear atypia seen in PMF is typically absent.[196-198] The marrow often shows increased blasts. Driver mutations in *JAK2, CALR,* and *MPL* are infrequent but have been identified in 5% to 10% of cases.[199,200] Leukoerythroblastosis and elevated LDH may be seen similar to overt PMF; however, splenomegaly is distinctly uncommon in MDS-F.[196-198,201]

Autoimmune myelofibrosis (AIMF) also needs to be distinguished from PMF. AIMF is a clinicopathological entity that can present as a primary disease known as primary AIMF or secondary to an established systemic autoimmune disorder. The marrow fibrosis of AIMF is usually responsive to steroids or other immunosuppressive therapy and has a generally favorable outcome. AIMF has been reported in association with systemic lupus erythematosus, Sjögren syndrome, Hashimoto thyroiditis, autoimmune hepatitis, and Evans syndrome (secondary AIMF); however, it can also be seen with autoantibodies, only without a defined disorder (primary AIMF).[202] Patients with AIMF commonly present with cytopenia, prompting a bone marrow biopsy for evaluation. The peripheral blood smear typically lacks leukoerythroblastosis or teardrop red cells. The bone marrow is often hypercellular, usually from erythroid hyperplasia. Megakaryocytes may be increased in number and pleomorphic; however, they lack tight clustering and nuclear atypia as seen in PMF (**Fig. 47-26**). Marrow fibrosis is usually mild (MF-1); however, some cases may show significant fibrosis (≥MF-2), raising the differential diagnosis of overt PMF. Lymphoid aggregates are common and predominantly composed of T cells. Variable plasmacytosis can be observed. AIMF lacks driver mutations *(JAK2, CALR, MPL)* and other clonal markers. Splenomegaly is uncommon in AIMF and, when present, is usually minimal and asymptomatic, although neutropenia and splenomegaly can occur in patients with rheumatoid arthritis (Felty's syndrome). The important clinical and morphologic differences between AIMF and PMF are included in **Table 47-7**.

Polycythemia Vera

Normally, erythropoiesis is fine-tuned to produce just the number of RBCs needed to carry oxygen to the tissues. Tissue hypoxia leads to an increase in production of EPO, the primary regulator of erythropoiesis. When EPO binds to EPOR on erythroid progenitors, there is dimerization of EPOR and phosphorylation of the associated JAK2 kinase, which in turn activates downstream effectors, including the JAK/STAT pathway, and culminates in the proliferation and reduced apoptosis of erythroid precursors.[203,204] Downregulation of EPOR and JAK2 signaling is mediated by protein tyrosine phosphatases such as SHP-1, by suppressors of cytokine signaling, and by other inhibitors of the activated pathways.[205] The synthesis of EPO occurs in peritubular cells in the kidney and is regulated by a family of transcription factors that are produced in response to hypoxia, the hypoxia-inducible factors (HIFs). HIFs undergo degradation through an interaction of HIF, oxygen, prolyl hydroxylase domain (PHD)-containing enzymes, and the von Hippel–Lindau tumor suppressor protein (VHL) as normal oxygen concentrations are reached. Under conditions of hypoxia, HIF degradation is slowed, and EPO synthesis is increased. Any disturbance in the synthesis of EPO or in the JAK/STAT pathway will result in too many or too few RBCs.[204]

Polycythemia is an increase in the number of RBCs per unit volume of blood, usually defined as a greater than two standard deviations increase from the age-adjusted, sex-adjusted, race-adjusted, and altitude-adjusted normal value for hemoglobin (Hb),

hematocrit, or RBC mass.[206] There are multiple causes of polycythemia. Polycythemia is usually a "true" increase in the RBC mass, but occasionally, diminished plasma volume leads to hemoconcentration and to "relative polycythemia." True polycythemia may be "primary," in which an intrinsic abnormality of erythroid progenitors renders them hypersensitive to or independent of factors that normally regulate their proliferation. More commonly, however, polycythemia is "secondary," in which case the polycythemia is caused by increased EPO that is caused by an appropriate physiologic response to tissue hypoxia or, occasionally, to inappropriate secretion of EPO by various neoplasms. Primary and secondary polycythemia may be acquired or congenital (**Box 47-10**).[204,206]

Definition

PV is an MPN predominantly characterized by increased RBC production independent of the mechanisms that normally regulate erythropoiesis. Almost all patients with PV have an acquired somatic gain of function mutation of the Janus 2 kinase gene, *JAK2* V617F, or less commonly, a functionally similar *JAK2* exon 12 mutation.[29-32] The diagnostic criteria of PV are listed in **Box 47-11**.

JAK2 mutations in PV encode a constitutively activated JAK2 kinase that binds to and activates non-TK cytokine receptors such as EPOR.[33,37] The *JAK2* mutation originates in a hematopoietic stem cell.[38] Because the JAK2 kinase binds not only with EPOR but with other non-TK receptors, including G-CSFR and MPL, granulocytes and megakaryocytes also carry the mutation and proliferate

autonomously, resulting in “panmyelosis” in the blood and marrow.[39]

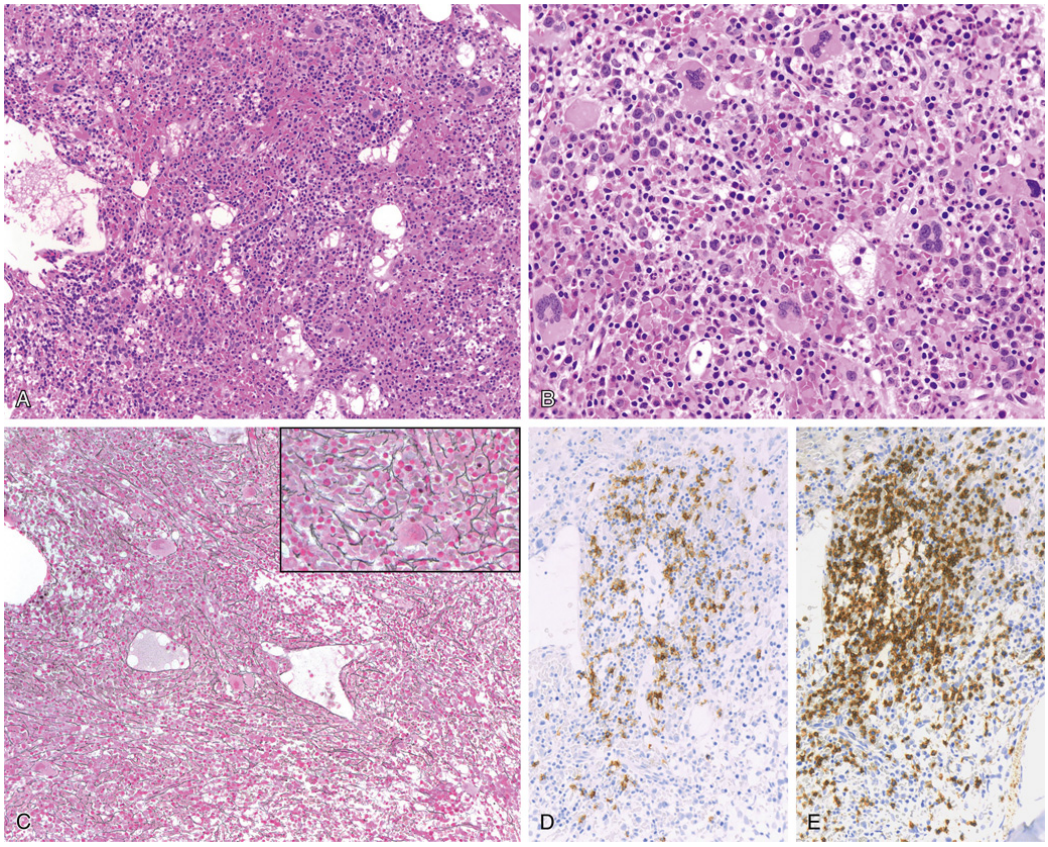

FIGURE 47-26 Autoimmune myelofibrosis.A, Hypercellular marrow with a few dilated sinusoids. **B,** Erythroid hyperplasia with increased megakaryocytes that are scattered in distribution and normal in morphology. **C,** Diffuse mild increase in reticulin fibers, MF-1. **D,** Lymphoid aggregate with few CD20-positive B cells. **E,** Lymphoid aggregate predominantly composed of CD3-positive T cells.

Synonyms and Related Terms

Polycythemia rubra vera, primary polycythemia

Epidemiology

PV is a rare disease, with an annual incidence of 1 to 3 per 100,000 individuals in the Western world; it is less common in Asia.[207,208] There is a slight male predominance. Most often, PV is encountered in patients in their 60s, and patients younger than 20 years are rarely described.[171]

Clinical Features

The principal symptoms are vascular disturbances caused by the increased RBC mass, including hypertension, thrombosis, and bleeding, which are also the leading causes of morbidity and mortality. Headache, dizziness, paresthesia, scotomas, and erythromelalgia are generally caused by thrombotic events in the microvasculature, but thrombosis involving major arteries or veins also occurs and can pose life-threatening events.[141] In particular, in case of splanchnic vein thrombosis and Budd-Chiari syndrome, a differential diagnosis of PV should always be considered. Fatigue, aquagenic pruritus, gout, and gastrointestinal complaints are additional symptoms. The most prominent physical findings include plethora in up to 80% of cases, palpable splenomegaly in 70%, and hepatomegaly in 40% to 50%.[209,210]

Morphology

The diagnosis of PV requires integration of clinical and laboratory data with histologic findings in adequate, well-prepared peripheral

blood smear and bone marrow biopsy specimens.

Peripheral Blood

The major hematologic finding in the blood is the increase in hemoglobin, hematocrit, and red blood cells.[211] Diagnostic thresholds have not been changed by the ICC, and PV is defined by an acquired increase in hemoglobin/hematocrit level above 16.5 g/dL or 49% in men and 16 g/dL or 48% in women, in the context of a *JAK2* mutation and characteristic bone marrow morphology.[1] The RBC indices are usually normal unless there is concomitant iron deficiency, in which case the mean corpuscular volume and mean corpuscular hemoglobin concentration may be low. Although not commonly measured in clinical practice, the red cell mass is >25% above the mean normal predicted value.[211] Neutrophilia and, rarely, basophilia may be present. Leukoerythroblastosis is not typically seen.

Table 47-7

CBC, Complete blood count; *LDH,* lactate dehydrogenase.

Bone Marrow

The bone marrow biopsy specimens show hypercellularity for age caused by erythroid, granulocytic, and megakaryocytic proliferation (panmyelosis; **Fig. 47-27**). Erythropoiesis is prominent, often occurs in expanded erythroid islands, and demonstrates normoblastic maturation. Granulopoiesis may show a shift toward immaturity, but there is no increase in the percentage of blasts and no significant dysplasia. Megakaryocytes are increased in number

and characteristically show increased pleomorphism with wide variation in their size. Although the megakaryocyte nucleus may be enlarged and/or irregularly folded, they do not demonstrate significant atypia such as presence of bizarre shapes or nuclear maturation abnormalities. They sometimes form loose clusters close to the bone trabeculae, but large dense clusters, which characterize PMF, are not seen in PV.[78,211] About 20% of patients exhibit a minimal increase in reticulin fibers (MF-1) at presentation, a finding associated with more rapid evolution to post-PV myelofibrosis.[212] A minority of cases show occasional reactive lymphoid follicles.[213] Marrow aspirate smears generally reflect these changes, but the diagnostic morphologic features are not as readily appreciated on smears as in biopsy sections. Stainable iron is absent in aspirate smears in most cases. Patients with PV and *JAK2* exon 12 mutations show clinical findings similar to those with *JAK2* V617F, although the bone marrow often shows primarily erythroid proliferation with less granulocytic and megakaryocytic expansion than that in patients with *JAK2* V617F.[41]

Box 47-10 Causes of Polycythemia

"True" Primary Polycythemia

- Congenital: primary familial congenital erythrocytosis, including EPOR mutations
- Acquired: polycythemia vera

"True" Secondary Polycythemia

- Congenital
- VHL mutations, including Chuvash polycythemia
- 2,3-Bisphosphoglycerate mutase deficiency
- High-oxygen-affinity hemoglobin
- Congenital methemoglobinemia
- Hypoxia-inducible factor 2α mutations
- Prolyl hydroxylase domain 2 mutations
- Acquired
- Physiologically appropriate response to hypoxia: cardiac, pulmonary, renal, and hepatic diseases; carbon monoxide poisoning; sleep apnea; renal artery stenosis; smoker's polycythemia; after renal transplantation*
- Inappropriate production of erythropoietin: cerebellar hemangioblastoma, uterine leiomyoma, pheochromocytoma, renal cell carcinoma, hepatocellular carcinoma, meningioma, parathyroid adenoma

Relative, "Spurious," or "False" Polycythemia

- Acute, transient hemoconcentration caused by dehydration or other causes of contraction of plasma volume; red cell mass is not increased, so it is not true polycythemia

---

* The cause of post-renal transplantation polycythemia is not clear; in some cases, it is likely from retained, chronically ischemic native kidney with endogenous erythropoietin

production plus increased sensitivity of the erythroid precursors to erythropoietin.

Box 47-11 Diagnostic Criteria* for Polycythemia Vera (PV) According to International Consensus Classification

Major Criteria

1. Elevated hemoglobin concentration or elevated hematocrit or increased red blood cell mass†
2. Bone marrow biopsy showing age-adjusted hypercellularity with trilineage proliferation (panmyelosis), including prominent erythroid, granulocytic, and increase in pleomorphic, mature megakaryocytes without atypia‡
3. Presence of *JAK2* V617F or *JAK2* exon 12 mutation§

Minor Criterion

1. Subnormal serum erythropoietin level

---

* The diagnosis of PV requires either all three major criteria or the first two major criteria plus the minor criterion.

‡ A bone marrow biopsy may not be required in patients with sustained absolute erythrocytosis (hemoglobin concentrations of >18.5 g/dL in men or >16.5 g/dL in women and hematocrit values of >55.5% in men or >49.5% in women) and the presence of a *JAK2* V617F or *JAK2* exon 12 mutation

† Diagnostic thresholds: hemoglobin: >16.5 g/dL in men and >16.0 g/dL in women; hematocrit: >49% in men and >48% in women; red blood cell mass: >25% above mean normal predicted value.

§ It is recommended to use highly sensitive assays for *JAK2* V617F (sensitivity level <1%); in negative cases, consider searching for noncanonical or atypical *JAK2* mutations in exons 12 to 15.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

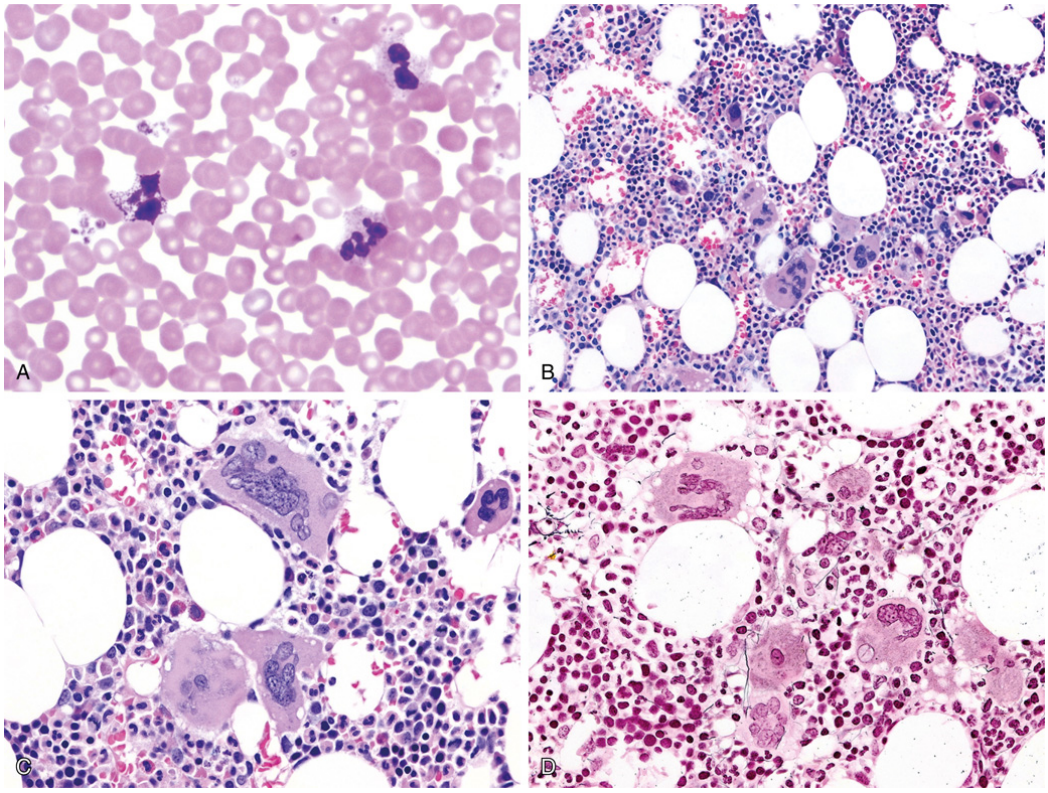

FIGURE 47-27 Polycythemia vera.A, Peripheral blood is characterized by mild neutrophilia and occasional basophils. **B,** Bone marrow biopsy reveals hypercellularity and panmyelosis. **C,** The megakaryocytes are variable in size and reveal hypersegmented nuclei, but overall, they are not atypical or bizarre. **D,** In the majority of cases diagnosed with PV, there is no significant increase in reticulin fibers.

Extramedullary Tissues

During the polycythemic phase, the splenomegaly is caused by engorgement of the cords and sinuses with RBCs, with minimal, if any, EMH. Similar changes may be seen in the hepatic sinuses.[214]

Genetics

More than 95% of patients with PV have the *JAK2* V617F mutation, and a *JAK2* exon 12 mutation is found in most of the remaining cases. Considering the central role of *JAK2* mutations in PV, it is important to recognize the need for diagnostic assays with <1% sensitivity.[215] Also, the possibility of other noncanonical *JAK2* mutations should be considered in *JAK2* V617F-negative cases with high suspicion of PV. The *JAK2* V617F mutation is not unique to PV; it is present in 50% to 60% of cases of ET and PMF, occasionally in MDS/MPNs, and in rare cases of AML. It is not clear what determines the disease phenotype in an individual patient, but the genetic background of the host and the dosage of the mutant allele may be important factors. Homozygosity for *JAK2* V617F, which results from mitotic recombination, is more common in PV than in other MPNs that carry the mutation. NGS analysis has revealed the presence of non-*JAK2* concomitant mutations in more than half of patients with PV, with the most frequent being *TET2, ASXL1,* and *SH2B3*.[142] In that particular study, *ASXL1, SRSF2, IDH2,* and *EZH2* mutations were associated with inferior survival.

Approximately 10% to 20% of patients with PV have karyotypic abnormalities at diagnosis, the most common of which are +8, +9, del(20q), and loss of Y.[216] An abnormal karyotype has been associated with inferior OS.[142]

Clinical Course

Thrombohemorrhagic complications represent the most common causes for morbidity and mortality in PV. Phlebotomy combined with aspirin is the most common form of therapy; but if the patient

has an increased risk for thrombosis, cytoreductive therapy may also be used.[141] OS in PV exceeds 13 years[141,217-219] and maybe as high as 37 years in younger patients (aged <40 years).[220] Risk factors for survival in PV include advanced age, leukocytosis, abnormal karyotype, *SRSF2* mutation, and treatment with pipobroman, chlorambucil, or 32P.[141,217] A mutation-enhanced prognostic scoring system (MIPSS-PV) includes age >60 years, *SRSF2* mutations, abnormal karyotype, and leukocyte count ≥11 × 10^9/L for a four-tiered survival model with an estimated median survival range of 5.4 to 25.3 years.[142] Reported rates of fibrotic progression in PV range from 6% to 14% at 15 years.[221] In younger patients (aged≤40years) with PV followed for a median of 11.3 years, fibrotic and leukemic progressions were reported in 22% and 4% of patients, respectively.[220]

During the later phases of PV, there is a progressive decrease in erythropoiesis, the RBC mass normalizes, and the panmyelosis in the marrow gives way to marrow failure accompanied by anemia, the so-called “spent phase.” Two additional patterns of disease progression are also recognized: post-polycythemia vera myelofibrosis (post-PV MF) and progression to BP.

Post-Polycythemia Vera Myelofibrosis

The progressive and often terminal complication of post-PV MF develops in approximately 15% of patients 10 to 15 years after the initial diagnosis of PV and in approximately 25% or more in those who survive 20 years or more.[222] The presence of marrow reticulin fibrosis at diagnosis predicts a higher incidence of such progression.[212] Post-PV MF is characterized by anemia, a

leukoerythroblastic blood smear with RBC poikilocytosis and teardrop-shaped RBCs, grade 2 or 3 fibrosis of the bone marrow, and splenomegaly caused by EMH.[211] The diagnostic criteria for post-PV MF are listed in **Box 47-12**. Bone marrow specimens are variably cellular but demonstrate overt reticulin and often collagen fibrosis and osteosclerosis (**Fig. 47-28**). Granulopoiesis and, particularly, erythropoiesis are diminished in quantity, and clusters of abnormal megakaryocytes of variable sizes with hyperchromatic, bizarre nuclei are frequently the predominant marrow component. Marrow sinuses are dilated and filled with hematopoietic precursors and megakaryocytes.[78] In the spleen, EMH in the cords and sinuses contributes to the leukoerythroblastosis in the blood. A similar pattern of EMH is seen in the liver. Nearly 80% to 90% of patients with post-PV MF exhibit an abnormal karyotype.[223]

Blast Phase/Myelodysplastic Phase

A myelodysplastic (MDS)-like phase and leukemic transformation are rare and usually late events in PV. The incidence in patients treated with only phlebotomy is 1% to 2%, which is assumed to be the incidence of MDS or acute leukemia in the natural course of disease.[222] The risk of development of these complications appears to be related to the patient's age (higher risk in older patients) and exposure to certain cytotoxic treatment modalities, such as alkylating agents and 32P, which are now rarely used in therapy for PV. In virtually all cases, the BP is myeloid and may be preceded by an MDS-like phase. The leukemic transformation may occur in the setting of post-PV MF. In such cases, fibrosis may prevent aspiration, and the detection of blasts in the biopsy may be facilitated by

staining for CD34. The finding of more than 10% blasts in the blood or marrow or severe myelodysplastic features, particularly in the granulocytic and erythroid lineages, generally supports accelerated or MDS-like phase, respectively, and 20% or more blasts indicates BP, i.e., overt acute leukemia. Almost all patients who have MDS features or leukemic transformation show karyotypic evolution, often with the acquisition of complex chromosomal abnormalities. However, at transformation, the leukemic blasts may not carry the *JAK2* V617F mutation, giving rise to speculation that the transformation arises from an abnormal clone that preceded the *JAK2* mutation.[224]

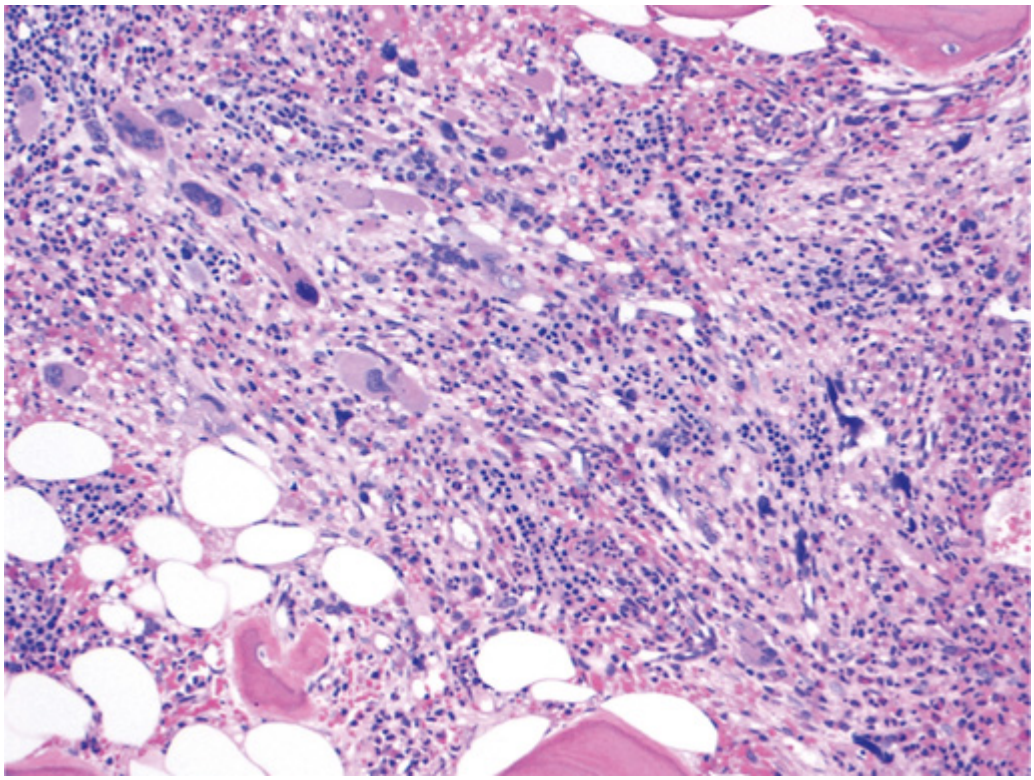

FIGURE 47-28 Post-polycythemia vera myelofibrosis (Post-PV MF). Bone marrow biopsy from a patient with polycythemia vera for nearly 15 years who then had anemia, leukoerythroblastosis, and increasing splenomegaly. The bone marrow is somewhat depleted, with a background of reticulin fibrosis and atypical megakaryocytes.

Box 47-12 Diagnostic Criteria* for Post Polycythemia Vera Myelofibrosis (post-PV MF) according to International Consensus Classification

Required Criteria

1. Previous established diagnosis of PV
2. Bone marrow fibrosis of grade 2 or 3

Additional Criteria

1. Anemia (i.e., below the reference range given age, sex, and altitude considerations) or sustained loss of requirement of either phlebotomy (in the absence of cytoreductive therapy) or cytoreductive treatment for erythrocytosis
2. Leukoerythroblastosis
3. Increase in palpable splenomegaly of >5 cm from baseline or the development of a newly palpable splenomegaly
4. Development of any two (or all three) of the following constitutional symptoms: >10% weight loss in 6 months, night sweats, unexplained fever (>37.5 °C)

* The diagnosis of post-PV MF is established by all required criteria and at least two additional criteria.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Differential Diagnosis

The different causes of polycythemia are listed in **Box 47-10**. Most cases encountered are either primary or secondary acquired polycythemia. Serum EPO levels and genetic testing for *JAK2* V617F

should be considered “up-front” tests for the diagnosis of PV and its differentiation from other causes of erythrocytosis.

Primary Polycythemia, Acquired and Congenital

PV is the only acquired primary polycythemia. The only congenital primary polycythemia that has been well characterized is primary familial congenital polycythemia, a rare condition caused by mutations in *EPOR,* usually with an autosomal dominant inheritance pattern.[225,226] These mutations lead to truncation of the cytoplasmic portion of EPOR and loss of the binding site of SHP-1, which normally downregulates EPO-mediated activation of the JAK2/STAT pathway. This results in hypersensitivity of the erythroid precursors to EPO.[204] As a consequence, serum EPO levels are low or normal. There is erythrocytosis but no granulocytosis or thrombocytosis. Patients are often asymptomatic but have a predisposition for development of cardiovascular disease. *EPOR* mutations account for only a small number of cases of primary familial congenital polycythemia; for the majority, the defect is unknown.[226] In some families, there is a predilection to develop PV or other MPNs because of a genetic factor that predisposes them to acquire a somatic *JAK2* mutation. Such cases should not be considered congenital polycythemia but familial primary acquired PV.

Secondary Polycythemia, Acquired and Congenital

The most common case of polycythemia is acquired secondary polycythemia induced by hypoxia. Chronic obstructive lung disease, right-to-left cardiopulmonary shunts, sleep apnea, and renal disease that compromises blood flow to the kidneys are the most frequent causes.[204,206] Individuals living at high altitudes compensate for the

lower atmospheric oxygen by increasing their Hb levels as a consequence of tissue hypoxia. Chronic carbon monoxide poisoning causes tissue hypoxia and is responsible, in part, for “smoker’s polycythemia”; nicotine also contributes by lowering plasma volume through its diuretic effect.

Inappropriate production of EPO is an often overlooked cause of secondary erythrocytosis. Cerebellar hemangioblastoma, uterine leiomyoma, pheochromocytoma, hepatocellular adenoma, and meningioma are among the tumors reported to be associated with EPO production.[204,206] Exogenous EPO administration to improve sports performance also leads to polycythemia; androgens have a similar effect. Post-renal transplantation polycythemia is a phenomenon of uncertain cause reported in 10% to 15% of renal transplant recipients 6 to 24 months after transplantation. Its incidence is decreasing and has been attributed to improvement in the immunosuppressive agents administered in the posttransplantation period.[227,228]

Congenital secondary polycythemia should be considered in young patients or in those with lifelong polycythemia in whom the serum EPO level is normal or elevated. Two broad groups of defects are found in this category—those associated with abnormal Hb affinity for oxygen and those associated with mutations of genes in the oxygen-sensing–EPO synthesis pathway. More than 90 Hb variants have been described with abnormal Hb-oxygen dissociation curves. Those with increased affinity for oxygen do not readily give up oxygen to tissues, and the oxygen dissociation curve is shifted to the left. This results in reduced P_{50}, and the resulting tissue hypoxia leads to increased EPO levels and secondary erythrocytosis.

Although some of the high-oxygen-affinity Hb variants are detected by electrophoretic techniques, a substantial number are not. Therefore, P_{50} is an appropriate screening test when an Hb variant is suspected. A similar effect is caused by the rare disorder 2,3-bisphosphoglycerate mutase deficiency.[204,227]

Mutations in genes encoding proteins in the oxygen-sensing pathway and in the synthesis of EPO do not result in abnormalities of the oxygen dissociation curve, and patients with these abnormalities have a normal P_{50}. Chuvash polycythemia is the most frequent of these disorders. This inherited form of secondary polycythemia affects individuals in the Chuvash region of Russia and is caused by a mutation in the von Hippel–Lindau *(VHL)* gene that results in inhibition of degradation of HIF-α, thus allowing increased EPO production. Mutations of the genes that encode the PHD-containing enzymes are also important in the degradation of HIF-α *(PHD2)* and of the genes that encode the HIF-α isoforms, which can lead to similar changes. Patients with mutations affecting these genes may have erythrocytosis as a result of increased serum EPO and are thus "secondary."[204,228]

Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL, NOS)

Considering the strict relationship of CEL, NOS with other myeloid neoplasms with eosinophilia, it has been described in detail in **Chapter 50**. **Box 47-13** lists the ICC criteria for diagnosis of CEL, NOS. A brief summary of CEL, NOS is included herein.

CEL is characterized by persistent eosinophilia not meeting the criteria for other genetically defined entities. The peripheral blood

demonstrates an absolute eosinophil count≥1.5 × 10^9/L and relative eosinophilia (≥10% of leukocytes). If a chronic myeloid neoplasm shows a relative and absolute eosinophilia without defining genetic lesions, a diagnosis of CEL, NOS supersedes a diagnosis of aCML, MDS/MPN-U, or MPN-U.

Ideally, a diagnosis of CEL, NOS is supported by the presence of clonal molecular genetic abnormalities and abnormal bone marrow findings or increased blasts. Mutations detected by NGS have helped to establish clonality in a significant subset of cases with eosinophilic disorders. Mutations in genes such as *ASXL1, TET2, EZH2, DNMT3A, SRSF2, TP53, SETBP1,* and *STAT5B* N642H have been identified.[229-231] Clonal cytogenetic or molecular alterations may not be demonstrated in all cases of CEL, NOS.

The bone marrow of CEL, NOS typically shows hypercellularity caused by a prominent proliferation of eosinophils and granulocytic cells. Megakaryocytes can show dysplastic features or a mixture of MDS-like and MPN-like features, with or without dysplastic features in other lineages. Significant marrow fibrosis (≥MF-2) is seen in 20% to 30% of cases. Cytologic abnormalities in a significant subset of eosinophils including abnormal granulation (hypogranular, uneven granulation), abnormal nuclear lobation (multilobation, hypolobation, nuclear branching), and large or markedly left-shifted forms are common; however, these findings are not specific to CEL, NOS. These abnormal bone marrow features are helpful in separating CEL, NOS from related entities such as idiopathic hypereosinophilic syndromes (iHES) and hypereosinophilia of unknown significance (HEus) and are now incorporated into the

diagnostic criteria. Except for increased eosinophils, the bone marrow in iHES and HEus is largely morphologically unremarkable.

Box 47-13 Diagnostic Criteria* for Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL, NOS) According to International Consensus Classification

1. Peripheral blood hypereosinophilia (eosinophil count ≥1.5 × 10^9/L and eosinophils ≥10% of white blood cells)
2. Blasts constitute <20% cells in peripheral blood and bone marrow, not meeting other diagnostic criteria for acute myeloid leukemia (AML)†
3. No tyrosine kinase gene fusion including *BCR*::*ABL1,* other *ABL1, PDGFRA, PDGFRB, FGFR1, JAK2,* or *FLT3* fusions
4. Not meeting criteria for other well-defined myeloproliferative neoplasms (MPNs); chronic myelomonocytic leukemia, or systemic mastocytosis‡
5. Bone marrow shows increased cellularity with dysplastic megakaryocytes with or without dysplastic features in other lineages and often significant fibrosis, associated with an eosinophilic infiltrate or increased blasts ≥5% in the bone marrow and/or ≥2% in the peripheral blood
6. Demonstration of a clonal cytogenetic abnormality and/or somatic mutation(s)§

---

* The diagnosis of CEL requires all six criteria.

‡ Eosinophilia can be seen in association with systemic mastocytosis (SM). However, “true” CEL, NOS may occur as SM with an associated myeloid neoplasm (SM-AMN).

† AML with recurrent genetic abnormalities with <20% blasts is excluded.

§ In the absence of a clonal cytogenetic abnormality and/or somatic mutation(s) or increased blasts, bone marrow findings supportive of the diagnosis will suffice in the presence of persistent eosinophilia, provided other causes of eosinophilia have been excluded.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

Myeloproliferative Neoplasms, Unclassifiable (MPN-U)

The designation MPN-U should be applied only to cases that have definite clinical, laboratory, and morphologic features of an MPN but fail to meet the criteria for any of the specific MPN entities or that present with features that overlap two or more of the MPN categories (**Box 47-14**).[1] Most cases fall into one of three categories: (1) early stages of PV, PMF, or ET in which the clinical, laboratory, and morphologic manifestations are not yet fully developed. Patients presenting with splanchnic vein thrombosis associated with *JAK2* mutation that fails to meet the diagnostic criteria for any of the specific MPN entities may also be considered to belong in this group; (2) advanced-stage MPN, in which myelofibrosis, osteosclerosis, or

transformation to a more aggressive stage obscures the underlying diagnosis; and (3) patients with convincing evidence of MPN in which a concomitant neoplastic or inflammatory process obscures the diagnostic clinical or morphologic classification. The designation MPN-U should not be used if laboratory data necessary for classification are incomplete or were never obtained, the size or quality of the bone marrow specimen is inadequate for complete evaluation, or the patient has received prior growth factor or cytotoxic therapy. In these instances, the morphologic features should be described with the suggestion of additional clinical and laboratory information that is necessary to accurately diagnose and classify the case. The finding of a *BCR*::*ABL1* fusion gene or rearrangements of *PDGFRA, PDGFRB, FGFR1,* or *PCM1*::*JAK2* precludes the diagnosis of MPN-U. Although *JAK2* V617F, *CALR,* and *CSF3R* mutations are most commonly observed in MPNs, they have been described in other myeloid neoplasms as well and cannot be used as the sole evidence to designate a case MPN-U if other data are not supportive.

Box 47-14 Diagnostic Criteria* for Myeloproliferative Neoplasm, Unclassifiable (MPN-U) According to International Consensus Classification

1. Clinical and hematologic features of an MPN are present[†]
2. *JAK2, CALR,* or *MPL* mutation[‡] or presence of another clonal marker[§]

3. Diagnostic criteria for any other MPN, MDS, MDS/MPN[¶] or chronic myeloid leukemia are not met

---

[*] The diagnosis of MPN-U requires all three criteria.

[‡] It is recommended to use highly sensitive assays for *JAK2* V617F (sensitivity level <1%) and *CALR* and *MPL* (sensitivity level 1% to 3%); in negative cases, consider searching for noncanonical *JAK2* and *MPL* mutations.

[†] In cases presenting with bone marrow fibrosis reactive causes must be excluded, in particular fibrosis secondary to infection, autoimmune disorder or another chronic inflammatory condition, hairy cell leukemia or another lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathy.

[§] Assessed by cytogenetics or sensitive NGS techniques; detection of mutations associated with myeloid neoplasms (e.g., *ASXL1, EZH2, IDH1, IDH2, SF3B1, SRSF2,* and *TET2* mutations) supports the clonal nature of the disease.

[¶] In cases presenting with myelodysplastic features effects of any previous treatment, severe comorbidity, and changes during the natural progression of the disease process must be carefully excluded.

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140(11):1200-1228.

If a case does not have features of one of the well-defined MPN entities, the possibility (or probability) that it is not an MPN must be seriously considered. Reactive bone marrow responses to a number

of inflammatory and infectious agents must be kept in mind, particularly when considering CNL and chronic eosinophilic leukemia. Marrow fibrosis with osteosclerosis may be found in some inflammatory and neoplastic conditions, including chronic osteomyelitis, Paget's disease, metabolic bone diseases, osteosclerotic myeloma, hairy cell leukemia, metastatic carcinoma, and malignant lymphoma.

When a diagnosis of MPN-U is made, the report should indicate why a more definitive diagnosis is not possible. If one or more specific MPNs can be excluded on the basis of the laboratory, clinical, and morphologic data available, that should be stated as well. Recommendations for additional studies to clarify the diagnosis should be given, even if it is only a suggestion to repeat the same studies after an appropriate time interval. Sharing the case with colleagues, particularly with the clinicians responsible for the patient's care, is important. Sending the case for an expert opinion may help reach a diagnostic conclusion or at least confirm that someone with more experience could not classify the case either.

Conclusion

The major categories of MPNs remain unchanged in the ICC and proposed WHO 5th edition. The diagnoses of these entities require an integrated approach incorporating clinical, morphologic, and genetic features. Continuous integration of new molecular data has improved understanding of the morphology and prognosis and have also helped refine the diagnostic criteria.

Acknowledgments

The authors graciously appreciate and acknowledge the work from the prior author, Dr. James Vardiman, who has inspired and contributed significantly to this updated chapter.

Pearls and Pitfalls

- Diagnosis of MPNs requires integration of clinical, laboratory, morphologic, and genetic findings.
- Increased peripheral blood counts are more common in the presence of reactive etiologies than neoplastic ones, and the former should be excluded before performing a bone marrow examination.
- Well-prepared peripheral blood and bone marrow aspirate smears and adequate bone marrow core biopsy specimens are essential for accurate diagnosis.
- Treatment and prognosis of MPNs require an accurate diagnosis. ET, PV, and pre-PMF can share similar presentation (e.g., thrombocytosis) and genetic findings (e.g., *JAK2* mutation). Bone marrow histology is required for reaching a correct diagnosis in *BCR*::*ABL1*-negative MPNs.
- Though megakaryocytic morphology and topography is important to distinguish between the various *BCR*::*ABL1*-negative MPNs, other features including cellularity, granulocytic-to-erythroid ratio, bone marrow fibrosis, clinical history, genetics, and laboratory data must be taken into consideration to make an accurate diagnosis.

- In cases of “triple-negative” ET and PMF, cytogenetics or NGS for mutations in genes associated with myeloid neoplasms can be helpful in establishing clonality.
- Although the diagnosis of CML is straightforward in most cases, it can have unusual manifestations that overlap with other myeloid neoplasms and reactive conditions, such as marked neutrophilia resembling CNL, thrombocytosis resembling ET, and monocytosis resembling CMML. Appropriate cytogenetic and molecular testing for *BCR*::*ABL1* fusion should be obtained in these cases.
- The threshold for leukocytosis in CNL varies depending on the presence or absence of activating *CSF3R* mutations.
- The diagnosis of MPN-U is not intended for cases with insufficient or inadequate diagnostic material, when there is lack of clinical information, or when appropriate preliminary laboratory workup has not been performed. In such cases, the report should specify what additional material or studies are required to render a conclusive diagnosis.

Introduction

The myelodysplastic syndrome/myeloproliferative neoplasm (MDS/MPN) category is a heterogeneous group of diseases characterized by the co-existence of clinicopathologic features of both MDS and MPNs. These disorders are also referred to as hybrid or overlapping myeloid disorders to reflect the fact that they harbor features of both MDS and MPNs.

In the International Consensus Classification (ICC), an update from the previous 2016 World Health Organization (WHO) revised 4th edition classification, neoplasms in the MDS/MPN diagnostic category include the following entities: chronic myelomonocytic leukemia (CMML), atypical chronic myeloid leukemia, MDS/MPN with *SF3B1* mutation and thrombocytosis, MDS/MPN with ring sideroblasts and thrombocytosis, not otherwise specified, and MDS/MPN, not otherwise specified (**Box 48-1**).[1-4]

Box 48-1 International Consensus Classification of Myelodysplastic/Myeloproliferative Neoplasms

Chronic myelomonocytic leukemia
Atypical chronic myeloid leukemia
Myelodysplastic/myeloproliferative neoplasm with *SF3B1* mutation and thrombocytosis
Myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis, not otherwise specified
Myelodysplastic/myeloproliferative neoplasm, not otherwise specified

- Includes the provisional subentity of myelodysplastic/myeloproliferative neoplasm with i(17q)

Additional related entries in the ICC include the pre-CMML conditions of clonal cytopenia with monocytosis of undetermined significance and clonal monocytosis of undetermined significance (**Box 48-2**).[3-5] These precursor conditions are somewhat comparable to those occurring in MDS.

The ICC stresses the concept that cases in the MDS/MPN diagnostic category should have at least one cytopenia and one cytosis by complete blood cell (CBC) analysis. The definition of cytopenia is anemia, Hb <13 g/dL (males), <12 g/dL (females); neutropenia, absolute neutrophil count (ANC) $<1.8 \times 10^9$/L; thrombocytopenia, platelets $<150 \times 10^9$/L.[6] One exception to requiring a cytopenia is in early stage CMML. A small proportion of

these patients may not be cytopenic, but a CMML diagnosis can still be made based on morphology and immunophenotypic and molecular data. As previously established cases of MPN may develop cytopenia(s) or monocytosis in the course of disease progression, it is essential that a diagnosis of MDS/MPN only be made for cases that did not have another preceding myeloid neoplasm.

Chronic Myelomonocytic Leukemia (CMML)

Definition

CMML is a clonal hematopoietic stem cell disorder with monocytosis and features of both MDS and MPN.[3,7,8] It is characterized by the presence of sustained (>3 months) peripheral blood (PB) monocytosis (≥0.5 × 10^9/L; monocytes ≥10% of white blood cell [WBC] count). Blasts, including promonocytes (which are considered blast equivalents), account for less than 20% of the cells in the PB and less than 20% of the nucleated cells in the bone marrow. The diagnostic criteria for CMML are presented in **Box 48-3**.

Data, particularly molecular genetics, has demonstrated that there is a similar mutational landscape between oligomonocytic CMML (cases with >10% circulating monocytes but an absolute monocyte count of 0.5 to <1.0 × 10^9/L) and traditional CMML (absolute monocytes ≥1.0 × 10^9/L). As such, they should be considered as one disease.[9,10] Consequently, in the presence of clonality, the criteria for diagnosing CMML now has a lower value of required absolute monocytosis, ≥0.5 × 10^9/L (modified from the 2016 WHO classification); however, monocytes must still account for ≥10% of the WBC count.

Box 48-2 International Consensus

Classification of Premalignant Clonal Monocytosis

Clonal monocytosis of undetermined significance

- Clonal cytopenia with monocytosis of undetermined significance

Box 48-3 Diagnostic Criteria for Chronic Myelomonocytic Leukemia (CMML)

MDS, Myelodysplastic syndrome; *WBC,* white blood cell count.

- Monocytosis defined as monocytes ≥0.5 × 10^9/L and ≥10% of the WBC
- Cytopenia(s)*—thresholds same as for MDS*
- Blasts/promonocytes <20% of the cells in peripheral blood and bone marrow
- Presence of clonality: abnormal cytogenetics and/or detection of at least one myeloid neoplasm–associated mutation of at least 10% variant allele frequency†
- In cases without evidence of clonality, monocytes must be ≥1.0 × 10^9/L and ≥10% of the WBC—AND—at least one of the following:
  - increased blasts/promonocytes‡

- morphologic dysplasia
- an abnormal immunophenotype consistent with CMML

- Bone marrow morphologic findings consistent with CMML (hypercellularity caused by a myeloid proliferation often with increased monocytes), and lacking diagnostic features of acute myeloid leukemia, myeloproliferative neoplasm, or other conditions associated with monocytosis[§]
- No *BCR*::*ABL1* or genetic abnormalities of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions

---

[*] Occasional cases may show no or borderline cytopenia(s) (usually in the early phase of the disease), but the diagnosis of CMML can still be made; anemia, Hb <13 g/dL [males], <12 g/dL [females]; neutropenia, absolute neutrophil count <1.8 × 10^9/L; thrombocytopenia, platelets <150 × 10^9/L.

[‡] Increased blasts: ≥5% in the bone marrow and/or ≥2% in the peripheral blood.

[†] Based on International Consensus Group Conference, Vienna, 2018 (Valent et al., 2019).

[§] For cases lacking bone marrow findings of CMML, a diagnosis of clonal monocytosis of undetermined significance could be considered. If a cytopenia is present, a diagnosis of clonal cytopenia and monocytosis of undetermined significance could be entertained. In these diagnostic settings, however, an alternative cause for the observed monocytosis must be excluded.

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid

neoplasms and acute leukemia. *Blood*. 2016;127(20):2391-2405.

Based on the WBC count, two distinct subtypes of CMML are recognized; the proliferative subtype (CMML-MP) (WBC ≥ 13 × 10^9/L) and the myelodysplastic subtype (CMML-MD).

Though the 2016 revision of the WHO classification introduced a three-tier classification of CMML, it has been shown that there is no clinical significance in separating CMML-0 (<2% blasts in PB and <5% blasts in bone marrow).[11,12] Therefore, based on the percentage of blasts and promonocytes (blast equivalents) in the blood and bone marrow, the ICC reverts to a two-tier system of CMML-1 (<5% blasts in PB, <10% in bone marrow) and CMML-2 (5%–19% blasts in PB, 10%–19% in bone marrow, or presence of Auer rods).

Synonyms and Related Terms

Chronic myelomonocytic leukemia (WHO 5th edition, Khoury 2022)[13]

Epidemiology

The incidence of CMML is not well defined; however, two studies have reported an approximate incidence of CMML as 2 to 4 cases per 100,000 persons/year.[14,15] However, the incidence may be higher because of misclassification (such as MDS or MPN) or bone marrow biopsies not being performed in older individuals.

Etiology

The etiology of CMML is unknown. Occupational exposures, environmental carcinogens, and ionizing radiation have been

suggested as possible causes in some cases. Therapy-related CMML has been described and is associated with a poor outcome.[16]

Clinical Features

CMML occurs commonly in older adults, with a median age at diagnosis of 65 to 75 years with a male-to-female ratio of 1.5 to 3.1. The clinical presentation of patients with CMML is highly variable and may manifest differently depending on whether it is the myeloproliferative or myelodysplastic variant. With the myeloproliferative variant (CMML-MP), patients often have "myeloproliferative-like" features such as leukocytosis, hepatosplenomegaly, fever, and night sweats.[17] Patients with high WBC counts are also more likely to have lymphadenopathy and leukemic skin infiltrates. There may be hemorrhagic episodes in up to 30% of patients and thrombotic complications in 10% to 15%; in some patients, early satiety caused by splenomegaly may be an initial complaint.[18] Approximately 30% of patients with CMML can present with manifestations of antecedent or concomitant autoimmune diseases (rheumatoid arthritis, psoriasis, etc.), vasculitic syndromes, classic connective tissue diseases, and poorly defined systemic inflammatory syndromes.

Morphology

Laboratory Findings

The WBC count is usually between 10 and 20 × 10^9/L. Uncommonly, cases may show a range of 2 to 500 × 10^9/L. Patients often have modest thrombocytopenia (80 to 100 × 10^9/L), and this is one of the

typical laboratory presentations (**Fig. 48-1B**). Anemia is usually mild and typically normocytic or macrocytic.

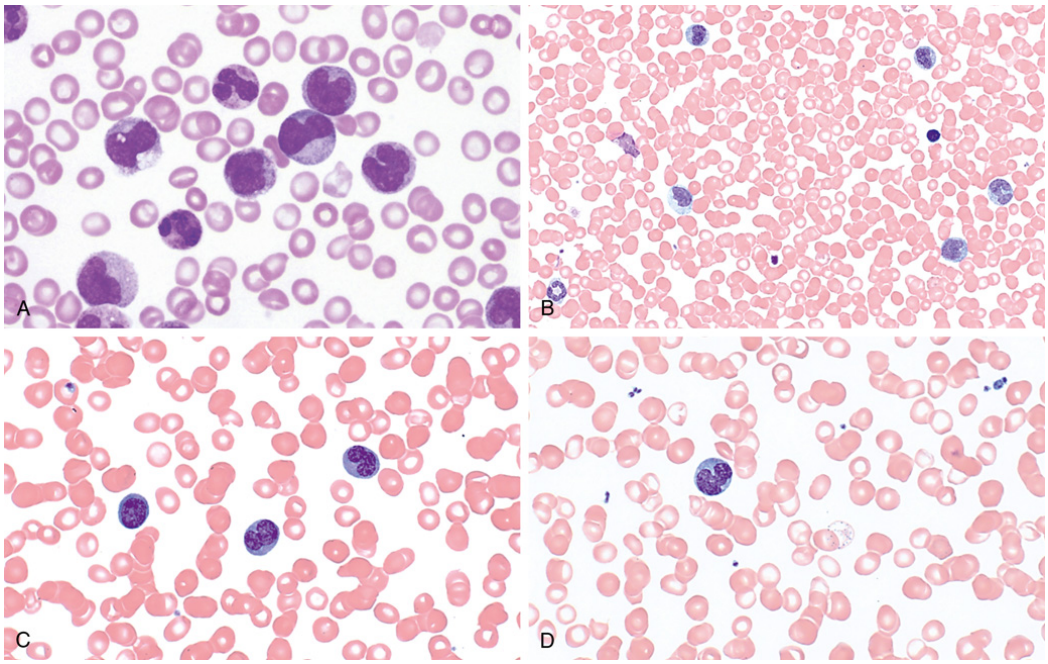

FIGURE 48-1 Peripheral blood findings in chronic myelomonocytic leukemia (CMML) (A–D). This composite photomicrograph demonstrates some typical peripheral blood features that may be encountered in CMML. **A,** Peripheral blood smear shows slightly elevated white blood cell count with absolute monocytosis and minimal dysplasia in the neutrophil lineage. **B,** Absolute monocytosis with abnormal appearing yet mature monocytes. Thrombocytopenia is notable in the background, which is common in CMML presentation. **C,** Abnormal-appearing monocytes with unusually clumped chromatin. **D,** Coarse basophilic stippling *(center of photographs)* in a case of CMML with ring sideroblasts.

By definition, monocytosis is present. The reported range of absolute monocytosis is impressive, varying from 0.5 to greater than 200×10^9/L, but in a significant majority of patients, monocytes are less than 5×10^9/L. Monocytes must account for 10% or more of the WBCs and are typically in the range of >15%, such that it is not a question as to whether monocytes are truly increased. This percentage is important because, in a number of diseases with elevated WBC counts, there may be only 1% to 2% monocytes in the leukocyte differential, but this can result in a significant so-called "absolute monocytosis."

Peripheral Blood

In CMML, the monocytes in the PB are typically mature, with minimal morphologic abnormality (**Fig. 48-1**). However, they can exhibit unusual nuclear lobation and delicate nuclear chromatin. When these latter features are present, the cells are best termed abnormal monocytes—this means the monocytes are atypical (**Fig. 48-2**) but lack the features of promonocytes (aka blast equivalents). Use of the term "immature monocytes" is confusing and, as such, should be avoided. Distinction between abnormal monocytes, promonocytes, and monoblasts is critical to not overestimate the blast percent (**Fig. 48-2**).

Promonocytes, which are blast equivalents, are cells with more delicately folded nuclei, thin nuclear slits, fine chromatin, small nucleoli, finely granular cytoplasm, and slightly less gray/more light-blue cytoplasm (Wright-Giemsa stain) (**Fig. 48-2B** and **C**). An increase in blasts in CMML may also be due to myeloblasts or monoblasts, or both. Monoblasts are large cells with abundant

cytoplasm that may contain a few vacuoles or fine granules; they have lacy, delicate nuclear chromatin and one or more nucleoli (**Fig. 48-2A**). Monoblasts exhibit a morphologic continuum with promonocytes (**Fig. 48-2B**), from which it may be difficult to distinguish them, but both cell types are considered together in tallying the number of blasts for classification purposes. Distinguishing myeloblasts, monoblasts, and promonocytes from the more mature "abnormal" monocytes and from normal monocytes is extremely important in distinguishing CMML from AML, although at times it may be problematic.[19] When blasts (myeloblasts, monoblasts, and promonocytes) account for 5% to 19% of the WBCs in the blood or 10% to 19% of the nucleated cells in the bone marrow, the diagnosis is CMML-2; if 20% or more are present in either location, the diagnosis is AML. The finding of Auer rods in blood or marrow cells also prompts the diagnosis of CMML-2 if blasts in the blood and marrow are less than 20%.

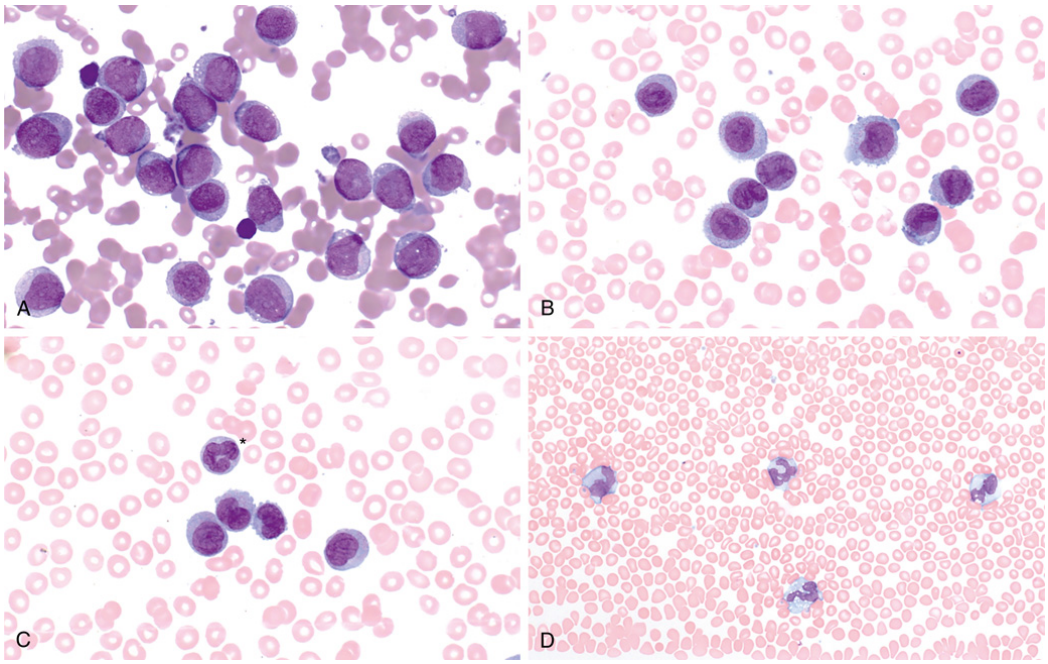

FIGURE 48-2 Monoblasts, promonocytes, and abnormal monocytes (A–D).A, Monoblasts are large, with round-to-oval nuclei that may be slightly irregular, lacy chromatin, one or more variably prominent nucleoli, and moderate to abundant, often moderately basophilic cytoplasm that may contain a few vacuoles or fine granules. **B** and **C,** Promonocytes have slightly irregular and slightly folded nuclei with delicate nuclear slits, fine chromatin, indistinct nucleoli, and moderate-to-abundant, light-blue/light-gray, finely granulated cytoplasm that may contain a few vacuoles. Promonocytes may have overlapping features with monoblasts. In some cases, one can appreciate the transition to a monoblast with an increase in overall cell size, increasing blue hue to the cytoplasm,

emergence of a nucleolus, and less irregular nuclear contours. In contrast to a promonocyte, an abnormal monocyte *(highlighted with an asterisk in **C**)* shows more nuclear lobation, less fine chromatin, absence of delicate nuclear slits, and grayer cytoplasm. **D,** Abnormal monocytes in CMML have more condensed chromatin; abnormally shaped, irregular, or folded nuclei; and abundant grayish (minimal blue) cytoplasm, with more cytoplasmic granules and, often, more cytoplasmic vacuoles.

Neutrophil precursors (promyelocytes, myelocytes, and metamyelocytes) typically account for less than 10% of the WBCs in the blood at diagnosis. Dysgranulopoiesis is uncommon and, if present at all, is seen in a substantial minority of cases. It has been suggested that patients with higher WBC counts have less dyspoiesis than those with lower counts, but in the opinion of the authors, there is no significant relationship between severity of dysplasia and the leukocyte count.

Platelets may exhibit dysplastic features such as being large and/or hypogranular. Indeed, in the setting of unexplained prolonged monocytosis and thrombocytopenia, dysplastic-appearing platelets may be the initial PB clue to the presence of a clonal myeloid disorder, including CMML.

Red blood cells may show a range of anisopoikilocytosis. In cases with macrocytic anemia, macrocytes may be present. If ring sideroblasts are present in the bone marrow, a dimorphic

appearance and coarse basophilic stippling (**Fig. 48-1D**) may be seen in circulating erythrocytes.

If a significant granulocytic left shift, granulocytic dysplasia, increased blasts, basophilia, or eosinophilia accompanies the monocytosis, it is incumbent upon the pathologist to exclude an alternative diagnosis (to CMML) such as chronic myeloid leukemia, *BCR*::*ABL1*-positive acute myeloid leukemia (AML), progression of an MPN with monocytosis, a myeloid neoplasm with eosinophilia, and a recurring genetic alteration involving a tyrosine kinase gene. These latter considerations are part of the exclusionary criteria in the diagnosis of CMML (**Box 48-3**).

Bone Marrow

Cellular bone marrow aspirate smears provide the best material for assessing the number of myeloblasts, monoblasts, promonocytes, and monocytes and for appreciating dysplasia in the various lineages (**Fig. 48-3A**). A granulocytic proliferation often left shifted is typically seen in the aspirate. Monocytes can be hard to identify. Cytochemical staining for alpha-naphthyl acetate esterase or alpha-naphthyl butyrate esterase to detect monocytes—either alone or in combination with naphthol AS-D chloroacetate esterase (CAE), which stains primarily neutrophils—can be very useful when the diagnosis of CMML is being considered (**Fig. 48-3B**). Dysgranulopoiesis, which is occasionally present, is more often appreciated in aspirate smears than in the PB. Dyserythropoiesis, particularly megaloblastoid changes or ring sideroblasts, is reported in about 25% of cases.

The bone marrow biopsy is hypercellular in more than 75% of cases (**Fig. 48-4**); rarely, normocellular or even hypocellular specimens may be encountered, but in the authors' opinion, the diagnosis should be questioned in these cases.[20,21] Granulocytic proliferation with left-shift, like the aspirate smears, is the most prominent feature in the biopsy, with a significant increase in the myeloid-to-erythroid ratio (**Fig. 48-4**). The number of megakaryocytes may be increased, normal, or decreased. Up to 75% of patients are reported to have micromegakaryocytes or megakaryocytes with abnormal nuclear lobation; however, in some cases, enlarged megakaryocytes can be found as well. Clustering of megakaryocytes is distinctly unusual in CMML.

The frequency of monocytes required in the bone marrow for the diagnosis of CMML has never been established, and the percentages reported in the literature vary widely; arguably, this is not relevant. However, in our experience, monocytes accounting for ≥10% of the marrow nucleated cells would indicate clear-cut bone marrow monocytosis. In well-fixed, thinly sectioned, and nicely stained biopsies, a proliferation of monocytes may be appreciated (**Fig. 48-4B**). Immunohistochemical stains such as CD14, CD68 (PG-M1), and CD163 can help their identification in histology sections (**Fig. 48-4**). An increase in blasts can be very difficult to appreciate in the biopsy because the granulocytes are left-shifted, and blasts/blast equivalents are often individually distributed and not in clusters, precluding their accurate recognition. In addition, clustering of myelocytes can be a morphologic distraction. In this situation, it is critical that one has a well-stained, well-sampled aspirate smear from which an accurate assessment of the blast count can be made. It

can also be difficult in some cases to distinguish hypogranular myelocytes from monocytes. In that regard, immunostains for a monocyte-associated marker such as CD14 is helpful. Staining of the biopsy specimen for CD34 may be useful in estimating the myeloblast percentage, but it is not helpful for assessing the monoblasts or promonocytes because these cell types are almost always CD34 negative.

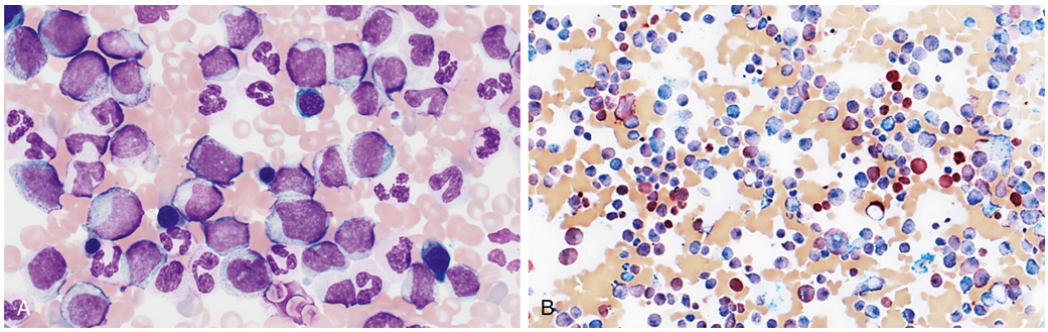

FIGURE 48-3 Bone marrow aspirate features in chronic myelomonocytic leukemia (CMML) (A, B).A, Well-stained, cellular bone marrow aspirate smears provide the best material for assessing the number of blasts, promonocytes, and monocytes and for appreciating dysplasia in the various lineages. **B,** Monocytic and granulocytic components in the bone marrow can be better appreciated with the combined esterase stains; chloroacetate esterase (CAE) combined with butyrate esterase (BE) *(monocytes are brown; neutrophils are blue)*. One will also notice increased dual esterase positive cells characterized by an admixture of both blue and brown staining.

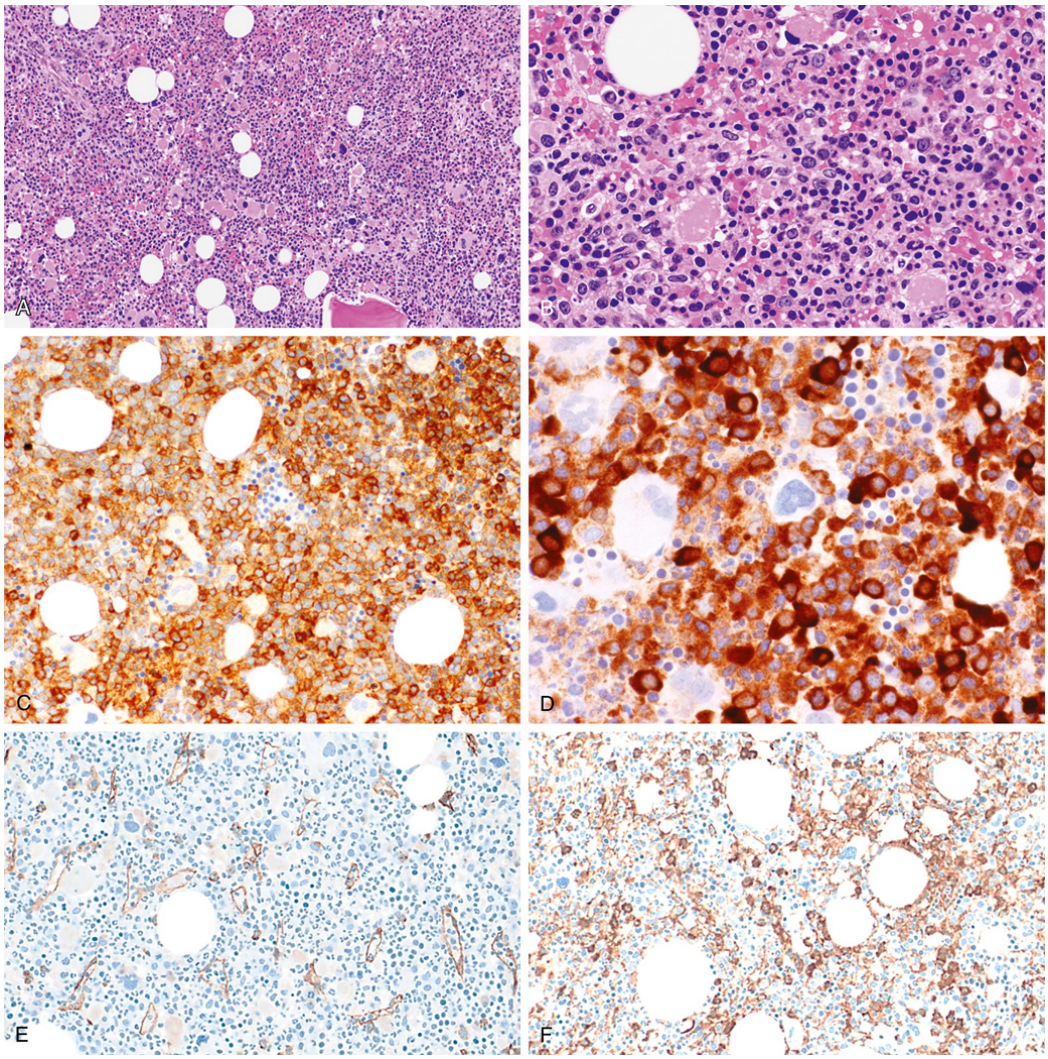

FIGURE 48-4 Bone marrow core biopsy morphologic and immunohistochemical features in chronic myelomonocytic leukemia (CMML) (A–F).A and **B,** The bone marrow is typically hypercellular with prominent, often left-shifted, granulocytic components. The increased number of monocytes cannot be appreciated at low magnification. Megakaryocytes may range in appearance from otherwise relatively normal appearing to small

dysplastic forms more often noted in the myelodysplastic variant of CMML to larger hyperlobulated forms, which may be seen in the myeloproliferative variant. **B,** On higher magnification, the folded nuclei of monocytes dispersed among the granulocytes can be better appreciated. Immunohistochemical stains for CD33 **(C)** and lysozyme **(D)** highlight the myelomonocytic components. **E,** In most cases of chronic myelomonocytic leukemia, an increase in true myeloblasts is infrequent but can be evaluated using a CD34 immunostain. It should be remembered that not all myeloblasts are CD34 positive. CD34 immunohistochemistry is not helpful in assessing for monoblasts and promonocytes because the cell types are almost always CD34 negative. **F,** Immunohistochemical staining for CD14 is very helpful in elucidating the increased monocytic component in chronic myelomonocytic leukemia. (H&E, 400× and 600× magnification; CD33, lysozyme, CD34 and CD14 immunohistochemistry).

Variably sized nodules of plasmacytoid dendritic cells, which strongly express CD123, can be found in the bone marrow core biopsy in approximately 30% to 40% of cases (Figs. **48-5** and **48-6**).[21] These findings are not specific for CMML but are a helpful clue. A proportion of cases may also be associated with systemic mastocytosis (**Fig. 48-7**), and when diagnosing CMML,

immunostaining for CD117 should always be performed to facilitate identifying the mast cells. If mast cells appear abnormally increased, the more specific (but often less sensitive) tryptase should be used to confirm their mast cell nature.

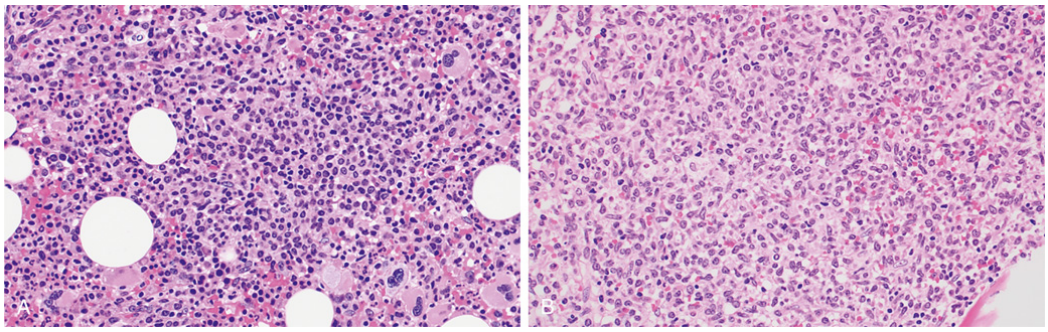

FIGURE 48-5 Plasmacytoid dendritic cell nodules in chronic myelomonocytic leukemia (CMML) (A, B). Plasmacytoid dendritic cell (pDC) nodules are seen in approximately 30% to 40% of cases of CMML. **A,** PDC nodules may be composed of a predominance of cells with a plasmacytoid type appearance characterized by small to intermediate sized cells with an eccentrically located round nucleus with an occasional small pinpoint nucleolus. **B,** Less commonly, pDC nodules may have a striking admixed spindle type of nuclear appearance characteristic of the dendritic origin of these cells.

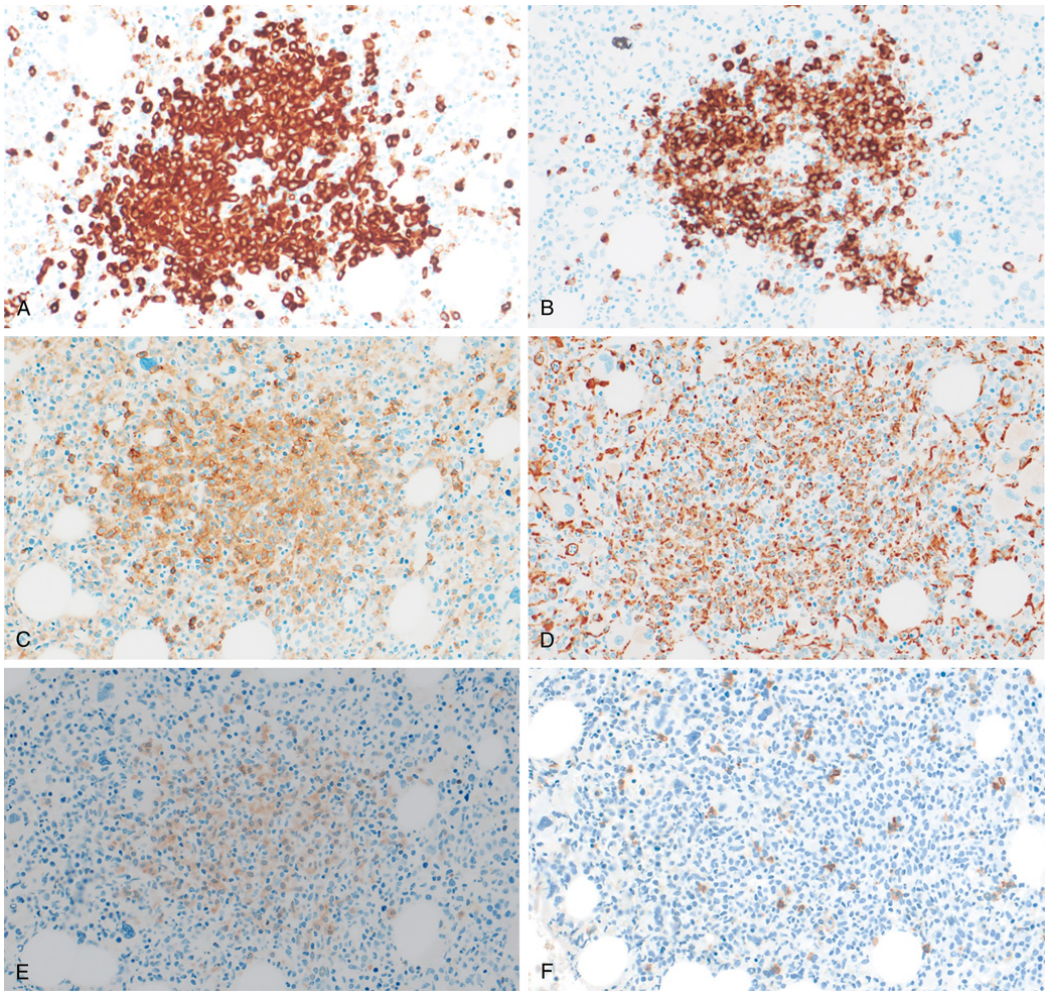

FIGURE 48-6 Immunohistochemical features of plasmacytoid dendritic cell nodules in chronic myelomonocytic leukemia (A–F). PDC nodules typically show the following immunophenotypic characteristics: Positive for CD123 **(A)**, CD303 **(B)**, CD4 **(C)**, CD68 (PG-M1 clone) **(D)**, TCL1A **(E)** and negative for CD56 **(F)**.

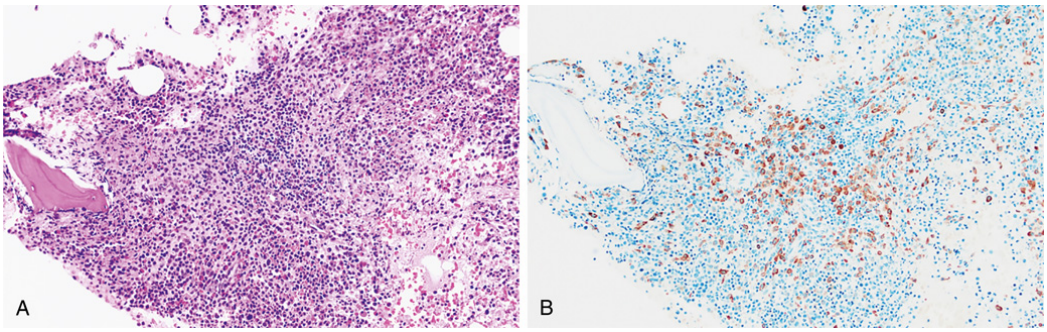

FIGURE 48-7 Chronic myelomonocytic leukemia (CMML) associated with systemic mastocytosis (A, B).A, A sneaky focus of systemic mastocytosis was seen in this case of CMML. As such, it is suggested to routinely perform a CD117 and/or tryptase immunostain in newly diagnosed cases of CMML to assess for the presence of occult systemic mastocytosis. **B,** A tryptase immunohistochemical stain identifies a focus of systemic mastocytosis in the setting of CMML.

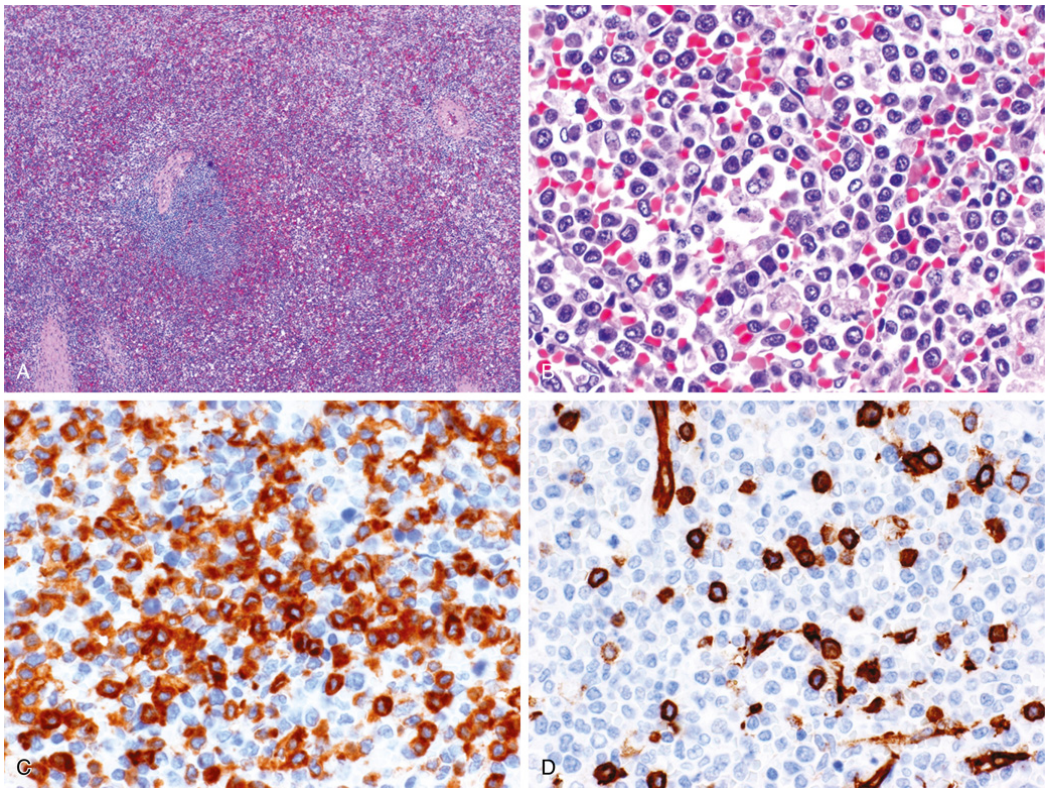

FIGURE 48-8 Spleen from a patient with chronic myelomonocytic leukemia 2.A, Leukemic infiltrate in the red pulp of the spleen encroaches on the white pulp. **B,** The infiltrate is composed of blasts, immature granulocytes, and monocytes. **C,** Immunohistochemical stain for CD14 highlights the monocytic component of the infiltrate. **D,** Immunohistochemical stain for CD34 demonstrates increased CD34-positive blasts.

Extramedullary Tissues

Splenic enlargement is frequent and is caused by leukemic infiltration of primarily the red pulp by myelomonocytic cells (**Fig.**

48-8). Trilineage extramedullary hematopoiesis has been reported in some splenectomy specimens from patients with CMML, and numerous foamy macrophages may be seen, particularly when the spleen has been removed as a therapeutic maneuver to relieve thrombocytopenia.[22] Some authors report high mortality and morbidity rates associated with splenectomy in patients with CMML.

Lymphadenopathy is seen in a minority of patients, and a biopsy is recommended in such cases because it may indicate extramedullary transformation to acute leukemia. In rare patients with CMML, tumoral proliferations of plasmacytoid dendritic cells, identical to those described in the bone marrow, may be seen in splenectomy or lymph node specimens.[23,24]

Cutaneous involvement can also be seen in CMML and rarely may be the initial presenting symptom. Plasmacytoid dendritic cells may also be part of abnormal skin proliferation.[25]

Immunophenotype

Immunohistochemistry on tissue sections of bone marrow biopsies is useful for assessing cellular components in their architectural context and may be helpful in distinguishing CMML (**Fig. 48-4**). Both granulocytes and monocytes, including immature forms and blasts, express CD33, which may be demonstrated in paraffin-embedded specimens (**Fig. 48-4C**). Immunostaining for lysozyme may help highlight granulocytic and monocytic components, but neither CD33 nor lysozyme can discern between them (**Fig. 48-4C and D**, respectively). Immunohistochemical staining for CD14 can be incredibly useful in the identification of increased monocytic cells (**Fig. 48-4F**). CD34 may help in estimating the myeloblast

percentage in the core biopsy specimen, but it is not helpful for assessing the monoblasts or promonocytes because these cell types are almost always CD34 negative (**Fig. 48-4E**). Markers such as CD68R (PG-M1), CD11b, CD11c, CD14, CD16, CD56, CD117, CD163, and HLA-DR are reportedly helpful in assessing the granulocytic and monocytic components of CMML, and some authors have suggested that, when a number of these markers are used in combination, the staining pattern may be useful in the differential diagnosis of CMML, aCML, and CML.[26-29]

Clusters of plasmacytoid dendritic cells associated with CMML can be identified with CD123 (**Fig. 48-7**).[21] Although seen more often in CMML than in MDS or MPN, these nodules are not specific to CMML. The cells are positive for antigens normally expressed by reactive plasmacytoid dendritic cells, such as CD4, CD68/CD68R, TCL1A, and CD303[30] (**Fig. 48-7**). In some cases, plasmacytoid dendritic cells may aberrantly express other antigens, such as CD2, CD5, CD7, CD13, or CD33. Recognition of this aberrant immunostaining is important because, in small or fragmented biopsies, an initial misdiagnosis of peripheral T-cell lymphoma is possible.

Multiparametric flow cytometry with carefully designed antibody panels allows for a comprehensive characterization of monocyte lineage maturation stages from early monocytic commitment of CD34-positive precursors to late mature monocytes and of the neutrophil maturation pathway from myeloid blasts to mature polynuclear neutrophilic granulocytes.[31,32] Abnormal antigen expression in blast, monocytic, and granulocytic compartments can be detected in many patients with CMML.[31-34] Comprehensive

antibody panels may therefore be helpful in the diagnosis of CMML and in follow-up by detection of phenotypic aberrancies associated with disease progression and regression of aberrancies in response to therapy.[35] By flow cytometric analysis, the leukemic cells express myelomonocytic antigens such as CD33 and CD13, with variable expression of CD14, CD36, and CD64. The monocytes in CMML often exhibit aberrant expression of two or more antigens, including overexpression of CD56; aberrant expression of CD2; and decreased expression of HLA-DR, CD14, CD11c, CD13, CD15, CD64, or CD36.

Several studies have shown that flow cytometric analysis of monocyte subsets may be useful to confirm the presence of distinct monocyte populations and distinguish reactive monocytic populations from those associated with CMML.[31,36,37] Based on the expression of CD14 and CD16, monocytes can be divided into classical (MO1, CD14 bright/CD16 negative), intermediate (MO2, CD14 bright/CD16 positive) and nonclassical monocytes (MO3, CD14 dim/CD16 positive), differing in phagocytic activities and inflammatory characteristics. By comparing healthy donors and patients with reactive monocytosis, Selimoglu-Buet et al. showed the percentages of classical monocytes in PB are higher, and the percentage of nonclassical monocytes is lower in patients with CMML.[36] Using a cutoff value of ≥94% classical monocytes, CMML cases can be identified by these authors with a sensitivity of 92% and a specificity of 94%. However, false negatives with this approach can be experienced, particularly in patients with CMML with autoimmune diseases, where the intermediate fraction increases (relative decrease in classical monocytes), and in other myeloid malignancies such as CML and atypical CML.[38] A study based on

real life experience has called into question the utility of this flow cytometric technique to distinguish the etiology of monocytosis.[39]

Cytogenetics

Clonal cytogenetic abnormalities are seen in approximately 20% to 30% of patients with CMML.[17] Common alterations include trisomy 8, abnormalities of chromosome 7, trisomy 21, deletion 20q, –Y, and complex karyotypes. No specific cytogenetic or genetic abnormalities have yet been identified in CMML, but the type of detected abnormality plays a role in risk stratification. In one study, survival analysis resulted in three cytogenetic risk categories: high (complex and monosomal karyotypes), intermediate (all abnormalities not in the high- or low-risk groups), and low (normal, sole –Y, and sole der [3q]). The overall median survivals in these three groups were 3, 21, and 41 months, respectively.[40]

Rearrangements of *KMT2A* (previously known as *MLL*) at 11q23.3 are not typical of CMML, and in the authors' opinion, detection of such rearrangements should be considered extraordinarily unusual. In such a situation, re-review of the entire case to exclude AML with a monocytic component is absolutely necessary.

Molecular Findings

Detection of pathogenic mutations can be diagnostically helpful in difficult cases of CMML/emerging CMML, particularly in cases with a normal karyotype or minimal/absent dysplasia. However, the molecular findings should always be integrated with the entirety of the case and not used solely to establish a final diagnosis. This is particularly true when only a single abnormality is detected at a low

variant allele frequency (VAF <10%) and in a gene that is associated with clonal hematopoiesis (CH) in normal aging individuals (e.g., *DNMT3A, TET2, ASXL1,* etc.).[41,42]

Somatic mutations are frequently found in patients with CMML.[17] These mutations can be subdivided into categories based on their role in the cell life cycle: histone modification *(EZH2, ASXL1)*, DNA methylation *(TET2, DNMT3A)*, spliceosome machinery *(SF3B1, SRSF2, U2AF1, ZRSR2)*, regulation of cell signaling (*JAK2, KRAS, NRAS, CBL, PTPN11,* and *FLT3*), transcription factors and nucleosome assembly regulators *(RUNX1, SETBP1)*, and DNA damage response genes such as *TP53*. Of these, mutations involving *TET2* (60%), *SRSF2* (50%), *ASXL1* (40%), and the *RAS* pathway (30%) are the most frequent. Overall, about 90% of patients with CMML exhibit one or more mutations, and concurrent mutations of *TET2* and *SRSF2* appear to be highly specific to CMML.[43-46] Multiple *TET2* mutations (aka multihit *TET2*) (defined as two or more *TET2* mutations/deletions and/or VAF ≥55%) also appear to be more frequent in CMML (including oligomonocytic CMML) than in MDS or MPN (approximately 50% versus 5%–6%).[47] In addition, the VAF of the first *TET2* hit is similar to the second *TET2* hit, in contrast to patients with MDS or MPN.[47] Though multihit *TET2* may show a higher percentage of peripheral blood/bone marrow monocytes and more dysgranulopoiesis than *TET2* wild-type patients, Garcia-Gisbert et al. did not observe statistically significant differences in OS between these two groups.[47]

Although the acquisition of genetic alterations remains an area of active investigation, it is believed that the initial driver mutation likely involves *TET2*. Second acquired alterations often include

another *TET2* and/or *SRSF2* mutation. *ASXL1, DNMT3A, RUNX1, SETBP1,* and *SF3B1* mutations are usually seen in the myelodysplastic subtype of CMML, whereas *RAS* pathway, and *JAK2* V617F mutations tend to occur in the myeloproliferative subtype of CMML.

Frame-shift and nonsense *ASXL1* mutations adversely affect OS in CMML; however, although frequent, *TET2* mutations do not. *ASXL1* mutations have been incorporated into prognostic scoring systems along with karyotype and clinicopathologic parameters.[48]

Mutations in *SF3B1* can be identified in <10% cases of CMML with frequent ring sideroblasts.[49] These cases have low frequency of *ASXL1* mutations and a superior AML-free survival compared with CMML cases lacking the *SF3B1* mutation.[50]

SETBP1 mutations in patients with CMML are associated with elevated WBC counts, more frequent extramedullary disease, more frequent *ASXL1* mutations, less frequent *TET2* mutations, and an adverse prognosis, suggesting distinct cooperative molecular events in *SETBP1*-mutated CMML.

Detection of an *NPM1* mutation is also distinctly unusual and should raise concern for AML. Though it is recognized that *NPM1* mutations may occur in chronic myeloid neoplasms,[51,52] careful scrutinization for an emerging AML is warranted.

Clinical Course

In view of the variable clinical, morphologic, and biological properties of CMML, it is not surprising that reported survival times differ widely. Although a median survival of 20 to 40 months is reported in most series, the range for individual patients is 1 month

to more than 120 months. Adverse prognostic factors vary depending on the study but may include thrombocytopenia (<100 × 10^9/L), transfusion history, severity of anemia, immature granulocytes in the blood (≥1%), serum lactate dehydrogenase greater than 700 U/L, an absolute lymphocyte count of 2.5 × 10^9/L or greater, bone marrow blasts exceeding 10%, and abnormal karyotype. Transformation of CMML to AML occurs in 20% to 30% of patients; more patients die of other complications, such as infection, without evidence of transformation.

There are several prognostic systems for CMML that facilitate predicting the clinical course for patients. In the Global MD Anderson prognostic system, four tiers of median survival have been identified: 54 months, 25 months, 14 months, and 6 months based on age, performance status, hemoglobin, platelet count, bone marrow myeloblast percentage, karyotype, leukocyte count, and transfusion history. The Mayo Clinic has derived a prognostic scoring system integrating the molecular alterations seen in CMML[53] based on five adverse independent prognostic factors: *ASXL1* mutations, absolute monocyte count >10 × 10^9/L, hemoglobin <10 g/dL, platelets <100 × 10^9/L, and circulating immature myeloid cells. In this model, they were able to show four risk categories (low, intermediate-1, intermediate-2, high) with median survivals of 97, 59, 31, and 16 months, respectively. The CMML-specific prognostic scoring system molecular model has also identified four risk groups (low, intermediate-1, intermediate-2, high): median OS not reached, 64, 37, and 18 months. With this stratification, the 4-year leukemic transformation rates of 0%, 3%, 21%, and 48%, respectively, were identified.[54]

Identifying the myelodysplastic versus myeloproliferative variant of CMML remains important. The myeloproliferative variant of CMML is associated with an adverse prognosis as captured by various CMML-specific prognostic scoring systems.[53,54] Also, given the potential difference in clinical behavior based on the different underlying genetic drivers, the separation of the myelodysplastic versus myeloproliferative variant of CMML may be of therapeutic benefit.

Currently, the only curative therapy for CMML is allogeneic stem cell transplantation; however, given that many patients are older and/or have multiple comorbid conditions, such treatment may not be an option. Hypomethylating agents (azacitidine and decitabine) are currently the most commonly used therapies for CMML.[17]

Differential Diagnosis

The diagnosis of CMML is often difficult—particularly when clinical history is minimal, dysplasia is minimal, the degree of monocytosis is slight/borderline, no cytogenetic abnormalities are present, and the duration of the monocytosis is unknown. As such, while one is awaiting the results of next-generation sequencing (NGS) results (if performed), there are multiple non-neoplastic and neoplastic conditions that should be considered in the differential diagnosis of CMML (**Box 48-4**).

Box 48-4 Differential Diagnosis of Chronic Myelomonocytic Leukemia

Infection (tuberculosis, syphilis, subacute bacterial endocarditis)
Autoimmune disease (rheumatoid arthritis, systemic lupus erythematosus, ulcerative colitis, polyarteritis)
Sarcoidosis
Malignant, nonmyeloid, disease (Hodgkin lymphoma, B-cell and T-cell lymphomas, carcinoma)
Myeloid neoplasm with rearrangements of *PDGFRA, PDGFRB, FGFR1, JAK2, FLT3, ABL1* (particularly when eosinophilia is present)
Atypical chronic myeloid leukemia
Acute leukemia with monocytic differentiation
Chronic myeloid leukemia, *BCR*::*ABL1* positive
BCR::*ABL1*-negative myeloproliferative neoplasms (e.g., primary myelofibrosis or polycythemia vera with monocytosis)
Myelodysplastic syndrome

Reactive Monocytosis

Reactive monocytosis is far more common than monocytosis occurring as a clonal condition. The hallmark of CMML—absolute monocytosis—is a non-specific finding associated with a wide variety of inflammatory and hematopoietic and non-hematopoietic neoplasms, all of which should be considered and excluded before a diagnosis of CMML is rendered. Viral, fungal, protozoal, rickettsial, and mycobacterial infections are commonly accompanied by monocytosis, as are autoimmune diseases and other chronic inflammatory disorders. Monocytosis is also common in patients

with lymphoma, particularly Hodgkin lymphoma, but may be found in other hematopoietic and non-hematopoietic malignant neoplasms as well.

The most important steps in distinguishing reactive monocytosis from CMML are a careful review of the clinical history for evidence of an underlying inflammatory or neoplastic disorder; physical examination to determine whether organomegaly is present (which would favor CMML); and inspection of the blood smear for evidence of dysplasia and morphologically abnormal or immature monocytes and for the absence of findings, such as in lymphoma cells, (which would support a different diagnosis). If, after these steps have been taken, the diagnosis of CMML is still being considered, a bone marrow specimen with appropriate genetic studies should be obtained to corroborate the diagnosis. Flow cytometric studies of the peripheral blood or bone marrow monocytes may provide useful information. The finding of >94% classical monocytes (repartitioning of monocytic subsets) or multiple aberrancies, such as overexpression of CD56 and underexpression of myeloid antigens on monocytes, supports the diagnosis of CMML. Nevertheless, reactive monocytes may also show aberrant phenotypes, and correlation with all the pathologic data is needed.

A prudent approach in all cases is to recognize that reactive monocytosis is more common than CMML. If dysplasia is lacking or minimal in the blood and bone marrow and there is no myeloid-related karyotypic abnormality or other genetic abnormality that clearly defines the process, it is best to give a descriptive diagnosis and to defer a definitive diagnosis until after an observation period of

3 to 6 months to ascertain that the monocytosis is persistent and that no underlying cause has been discovered.

Acute Myeloid Leukemia With Monocytic Differentiation

Acute leukemia must always be considered in the differential diagnosis of CMML, particularly CMML-2. A bone marrow aspirate and biopsy are crucial in distinguishing between these entities because blasts and promonocytes are usually more prominent in the bone marrow than in the blood. Even in bone marrow specimens, the blasts may be irregularly distributed, and inspection of both the biopsy and aspirate together yields the most useful information. Moreover, the distinction between monocytes, abnormal monocytes, promonocytes, and blasts is sometimes difficult,[19] and distinguishing some cases of AML from CMML-2 can be challenging. When the number of blasts plus promonocytes is 20% or more in the blood or bone marrow, the diagnosis is AML rather than CMML. An additional difficulty is the finding of mutated *NPM1* in a case in which the diagnosis of CMML is being considered. In such cases, close follow-up and aggressive clinical intervention are suggested, as mutated *NPM1* is generally regarded as an AML-related mutation.[52]

Chronic Myeloid Leukemia, *BCR*::*ABL1* Positive

The distinction between CML, *BCR*::*ABL1* positive and CMML is made on the basis of morphology combined with cytogenetics and molecular genetic studies; the *BCR*::*ABL1* fusion gene is always present in CML and never present in CMML. In rare cases of CML, the BCR breakpoint is in the minor breakpoint cluster region, which leads to production of the p190 fusion protein, which is smaller than the p210 protein found in almost all cases of CML. The p190 protein

is usually associated with Philadelphia (Ph) chromosome–positive acute lymphoblastic leukemia, but rare cases with this breakpoint may initially be CML with a chronic phase that exhibits increased numbers of monocytes, mimicking CMML (**Fig. 48-9**). Therefore, cytogenetic and genetic testing for the *BCR*::*ABL1* fusion gene is strongly recommended whenever the diagnosis of CMML is considered.

Myeloid Neoplasms Associated With Eosinophilia and Rearrangements of *PDGFRB*

The initial cases of rearrangement of *PDGFRB* and some subsequently reported cases had features of CMML with eosinophilia. However, the finding of this rearrangement and of rearrangements of *PDGFRA, FGFR1, JAK1, FLT3*, and *ABL1* excludes the diagnosis of CMML; such cases are classified according to the specific gene involved.

Atypical Chronic Myeloid Leukemia

This entity is discussed in detail later in this chapter. Briefly, aCML has many similarities to CMML, but it can be distinguished by the percentage of monocytes in the PB (rarely >2% to 4% and always <10% in aCML) and by the more severe granulocytic dysplasia in aCML. The use of cytochemistry for non-specific esterase to detect monocytes in the blood and bone marrow can be invaluable in difficult cases. Because the prognosis for aCML is particularly poor, its distinction from CMML is of clinical importance.

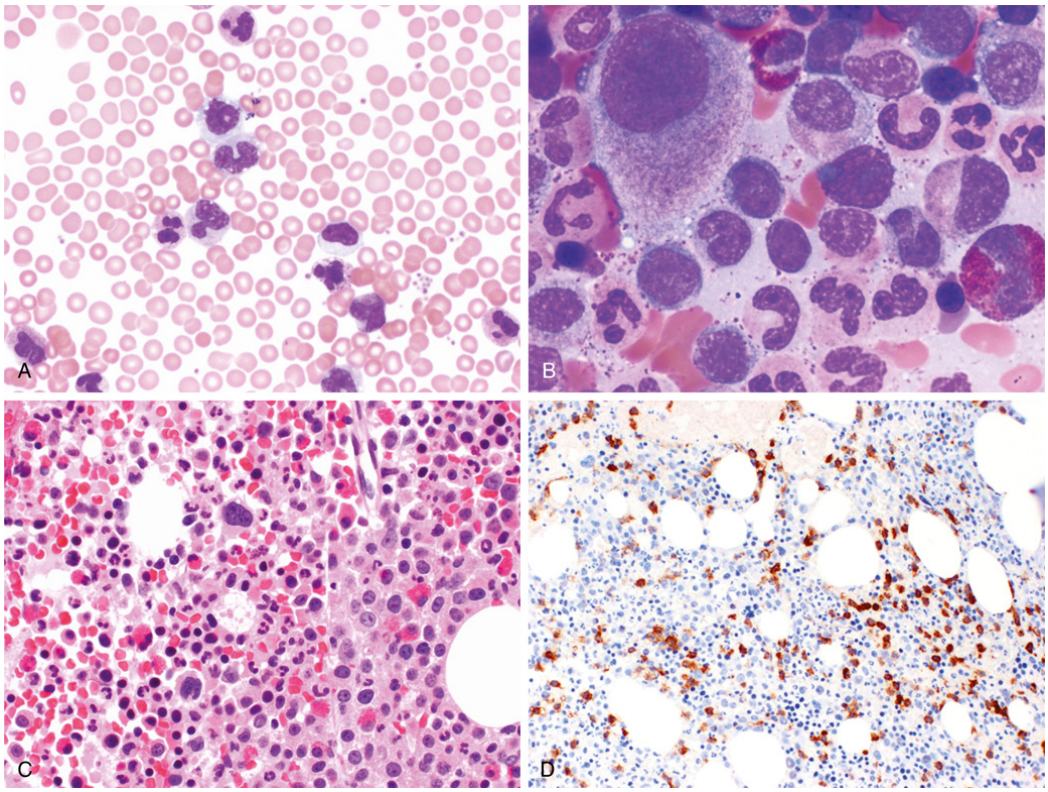

FIGURE 48-9 Chronic myeloid leukemia, *BCR*::*ABL1* positive (with p190 fusion protein) mimicking chronic myelomonocytic leukemia.A, Peripheral blood smear demonstrates leukocytosis with monocytosis, circulating granulocytes at all stages of maturation, and basophilia. **B** and **C,** Bone marrow aspirate smear **(B)** and bone marrow biopsy **(C)** demonstrate monocytosis, with granulocytic proliferation and small, hypolobated megakaryocytes. **D,** Immunohistochemical stain for CD14 highlights increased monocytes.

BCR::*ABL1*-Negative Myeloproliferative Neoplasms Associated With Monocytosis

Monocytosis can occur in *BCR*::*ABL1*-negative MPNs such as primary myelofibrosis and polycythemia vera; it is considered a form of disease progression and adversely affects survival.[55,56]

Because CMML may be associated with prominent reticulin fibrosis,[57] its differentiation from primary myelofibrosis and other MPNs can be difficult. In such cases, the bone marrow biopsy finding of clusters of pleomorphic, bizarre megakaryocytes that range in size from small to large with abnormal, bulky nuclei may be the most helpful distinguishing feature; tight clusters of such bizarre megakaryocytes are rarely observed in CMML.[58,59] The *JAK2* VAF may also be a useful discriminating factor.[60]

Myelodysplastic Syndrome

Cases of CMML with normal or even low WBC counts and prominent dysplasia may be difficult to distinguish from MDS, particularly at an early stage of presentation. Despite the similarities with MDS, if the ICC criteria are carefully applied, the finding of monocytosis of at least 0.5×10^9/L is sufficient for a diagnosis of CMML rather than MDS, assuming the bone marrow findings and other diagnostic features support such an interpretation. Rarely, MDS cases can transform to "secondary" CMML during the course of disease.[61]

Clonal Cytopenia With Monocytosis of Undetermined Significance and Clonal Monocytosis of Undetermined Significance

The concept of CH occurring in normal individuals without a hematologic malignancy has its origins in several articles from the

last decade.[41,42] Targeted NGS most often reveals single genetic mutations (e.g., *ASXL1, TET2, DNMT3A*) at variant allele frequencies of less than 10% in these individuals. Similarly, these alterations may be detected in some individuals with unexplained cytopenia(s) and no dysplasia—the latter being termed as clonal cytopenia of uncertain significance (CCUS).

It has similarly been noted that some individuals with CH may exhibit persistent unexplained mild monocytosis. These cases do not meet the criteria for CMML, and as such, this raises the distinct possibility that they represent a precursor state to CMML or other MDS/MPD; however, it is likely that only a small subset will develop a true hematologic malignancy (similar to CCUS). In these patients, the types of myeloid mutations, number of mutations, and VAF tend to overlap with CMML, but it is not a perfect correlation. As mentioned, it does appear that these individuals carry a higher risk of developing an overt myeloid malignancy.[62-64]

As a result of these findings, the ICC recognizes that there is a CMML precursor condition of CMUS.[3,4] This is based on the following criteria: absence of cytopenia, persistent monocytosis (monocytes ≥10% and ≥0.5 × 10^9/L of the WBC), presence of myeloid neoplasm–associated mutation(s), and absence of bone marrow morphologic findings of CMML. If cytopenia(s) is also present, then the ICC recommends the terminology of clonal cytopenia and monocytosis of undetermined significance (CCMUS). **Box 48-5** delineates the diagnostic criteria for CMUS and CCMUS.

Atypical Chronic Myeloid Leukemia (aCML)

Definition

aCML is a clonal hematopoietic stem cell disorder that exhibits myelodysplastic and myeloproliferative features with characteristic granulocytic leukocytosis and dysplastic neutrophils. It is a diagnosis of exclusion, requiring clinical history, especially for possible antecedent myeloid neoplasms or prior chemotherapy, comprehensive genetic testing, exclusion of eosinophilia, and methodical evaluation of leukocytes in the blood and bone marrow.[3,65] The term aCML is quite unfortunate, as it is of no relation to CML, *BCR*::*ABL1* positive. Diagnostic criteria are shown in **Box 48-6**.

Synonyms and Related Terms

Atypical chronic myeloid leukemia, *BCR*::*ABL1* negative; atypical chronic myeloid leukemia, Ph chromosome negative; MDS/MPN with neutrophilia (WHO 5th edition, Khoury 2022)[13]

Epidemiology

The incidence of aCML is unknown. Although a number of reports have described patients with aCML, only a few have adhered to the diagnostic criteria first established by the French-American-British Cooperative Group and later adopted by the WHO.[65-67] Most cases occur in patients in the 7th or 8th decade of life, but younger patients may be affected as well.[67-69] The reported male-to-female ratio varies.

Etiology

The etiology of aCML is unknown.

Clinical Features

Symptoms related to anemia or thrombocytopenia are most frequently mentioned, but the chief complaint may also be related to splenomegaly.[67,69] Patients with aCML tend to be elderly, with the median patient age at diagnosis in the 7th or 8th decade of life.

Box 48-5 Diagnostic Criteria for Clonal Monocytosis of Undetermined Significance (CMUS)

CMML, Chronic myelomonocytic leukemia; *MDS,* myelodysplastic syndrome; *WBC,* white blood cell count.

- Persistent monocytosis defined as monocytes ≥0.5 × 10^9/L and ≥10% of the WBC
- Absence or presence of cytopenia (thresholds same as for MDS)* (anemia, Hb <13 g/dL [males], <12 g/dL [females]; neutropenia, absolute neutrophil count <1.8 × 10^9/L; thrombocytopenia, platelets <150 × 10^9/L)†
- Presence of at least one myeloid neoplasm-associated mutation of appropriate allele frequency (i.e., ≥2%)*
- No significant dysplasia, increased blasts/promonocytes, or morphologic findings of CMML on bone marrow examination‡
- No criteria for a myeloid or other hematopoietic neoplasm are filled
- No reactive condition that would explain a monocytosis is detected

* Based on International Consensus Group Conference, Vienna, 2018 (Valent et al., 2019).

‡ Bone marrow findings of CMML include hypercellularity with myeloid predominance, often with increased monocytes and in a proportion of cases monoblasts and/or blast equivalents (i.e., promonocytes) and/or dysplasia in at least one lineage.

† If a cytopenia is present, the nomenclature of clonal cytopenia and monocytosis of undetermined significance (CCMUS) is suggested.

Box 48-6 Diagnostic Criteria for Atypical Chronic Myeloid Leukemia (aCML)

- Leukocytosis ≥13 × 10^9/L, caused by increased numbers of neutrophils and their precursors (promyelocytes, myelocytes and metamyelocytes), the latter constituting ≥10% of the leukocytes
- Cytopenia(s) (thresholds same as for myelodysplastic syndrome [MDS])* (anemia, Hb <13 g/dL [males], <12 g/dL [females]; neutropenia, absolute neutrophil count <1.8 × 10^9/L; thrombocytopenia, platelets <150 × 10^9/L)
- Blasts <20% of the cells in blood and bone marrow
- Dysgranulopoiesis, including the presence of abnormal hyposegmented and/or hypersegmented neutrophils and abnormal chromatin clumping
- No or minimal absolute monocytosis; monocytes constitute <10% of the peripheral blood leukocytes

- No eosinophilia; eosinophils constitute <10% and <1.5 × 10^9/L of the peripheral blood leukocytes
- Hypercellular bone marrow with granulocytic proliferation and granulocytic dysplasia, with or without dysplasia in the erythroid and megakaryocytic lineages
- No *BCR*::*ABL1* or genetic abnormalities of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions. The absence of myeloproliferative neoplasm–associated driver mutations and the presence of a *SETBP1* mutation in association with an *ASXL1* pathogenic variant provide additional support for a diagnosis of aCML.

* Based on International Consensus Group Conference, Vienna, 2018 (Valent et al., 2019).

Morphology

Blood

The WBC count is always greater than 13 × 10^9/L, with median reported values ranging from 32 to 96 × 10^9/L. Occasionally, some patients have WBC counts in excess of 300 × 10^9/L.[68,69] Granulocytic precursors (promyelocytes, myelocytes, and metamyelocytes) constitute ≥10% of the leukocytes. Thrombocytopenia is often present and may be severe, but thrombocytosis can occur as well. Anemia is usually present.

The peripheral blood smear is most remarkable for pronounced dysgranulopoiesis (**Fig. 48-10**). Neutrophils, many with hypogranular cytoplasm and abnormally lobated nuclei, usually

predominate. Prominent nuclear clumping of neutrophils is also a feature (**Fig. 48-11**).[70-72] Immature neutrophils (promyelocytes, myelocytes, metamyelocytes) account for at least 10% or more of the WBCs, but the percentage of blasts is always less than 20% (usually less than 5%). In most cases, basophils account for 2% or less of the WBCs. It is important to enumerate monocytes carefully because they are a key feature in distinguishing aCML from CMML. In aCML, slight absolute monocytosis may be present, but the monocyte percentage is always less than 10% of the WBCs. Evidence of dyserythropoiesis, such as macroovalocytosis, is commonly observed.

Bone Marrow

The bone marrow is hypercellular and shows a predominantly granulocytic proliferation (**Fig. 48-10**). Blasts may be modestly increased in number but are always less than 20% of the nucleated bone marrow cells. In cases with a suboptimal aspirate smear or in cytologically difficult cases, blast identification may be facilitated by staining biopsy sections for CD34, being careful to remember that not all blasts are CD34 positive. As in the peripheral blood smear, granulocytic dysplasia is marked and can even be appreciated in the biopsy (**Fig. 48-11**). Megakaryocytes vary in number, with most cases displaying some degree of megakaryocytic dysplasia similar to that observed in MDS (small megakaryocytes with abnormal, hypolobated nuclei). Dyserythropoiesis is found in more than 50% of cases. Reticulin fibers are increased in some patients at the time of diagnosis and may increase during the course of the disease.

Cytochemical staining of the bone marrow for non-specific esterase, either alone or in combination with CAE, is strongly recommended to assess the percentage of monocytes and to help distinguish aCML from CMML. Immunohistochemical staining of the marrow biopsy specimen can also be helpful, but it is often not as sensitive as cytochemical techniques.

Most cases reported as the syndrome of abnormal chromatin clumping can be considered variants of aCML.[70,71] These are characterized in the blood and bone marrow by a high percentage of neutrophils and precursors, with exaggerated clumping of the nuclear chromatin (**Fig. 48-11**).

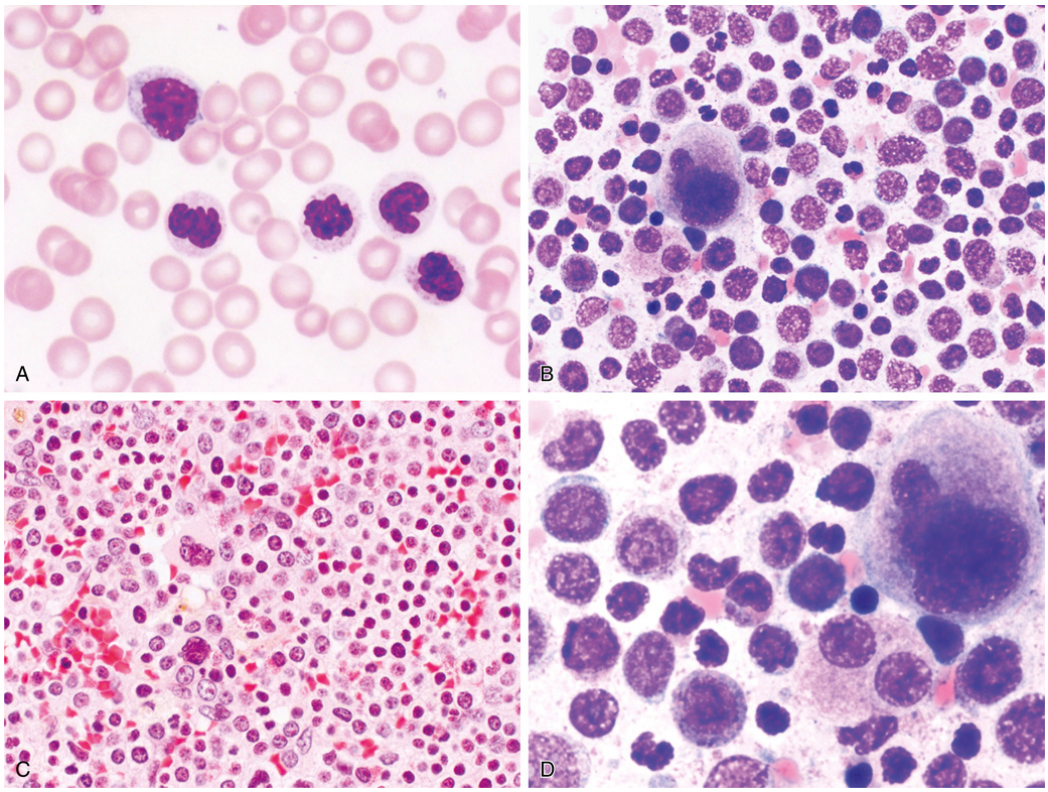

FIGURE 48-10 Atypical chronic myeloid leukemia.A, Peripheral blood smear shows elevated white blood cell count, with marked granulocytic dysplasia and immature granulocytes. **B,** Bone marrow aspirate smear shows granulocytic and megakaryocytic dysplasia. **C,** Bone marrow biopsy is hypercellular because of granulocytic proliferation with dysplasia and dysmegakaryopoiesis. Cells with clear cytoplasm are dysplastic granulocytes with marked pseudo–Pelger-Huët changes. **D,** On higher magnification, granulocytic and megakaryocytic dysplasia can be better appreciated.

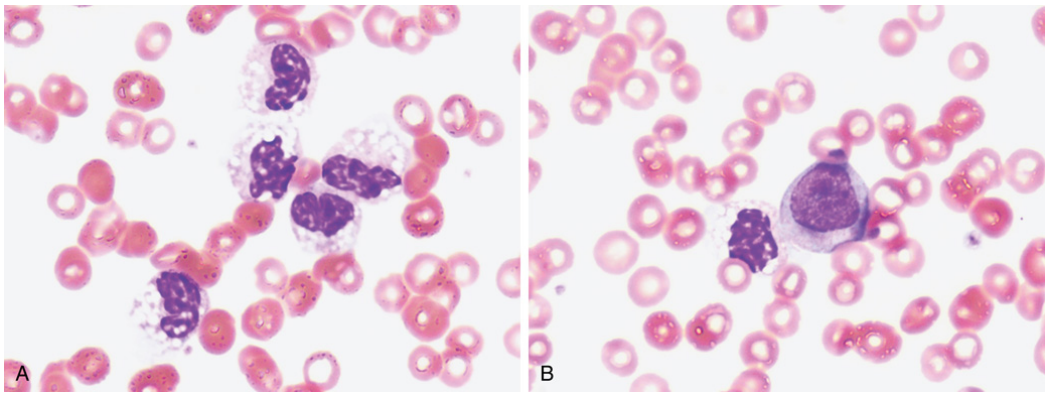

FIGURE 48-11 Atypical chronic myeloid leukemia: "syndrome of abnormal chromatin clumping" variant.A and **B,** Peripheral blood smear shows marked granulocytic dysplasia, with abnormally lobated nuclei, clumped chromatin, and immature neutrophils.

Immunophenotype

No specific immunophenotypic characteristics have been reported. By multiparameter flow cytometry, however, asynchronous expression of maturation antigens on the myeloblasts and maturing granulocytes, similar to that reported in MPNs and MDS, would be expected. Similarly, there is abnormal (decreased) side-angle light scatter properties caused by the hypogranular cytoplasm of granulocytes. Immunohistochemistry may be helpful in some cases. CD14 and CD163 may highlight increased monocytic cells, which if present, should call into question an alternative diagnosis such as CMML. CD61 may facilitate recognition of small, dysplastic megakaryocytes.

Cytogenetics/Molecular Findings

Karyotypic abnormalities are reported in up to 80% of patients with aCML.[3] The most common chromosome abnormalities include trisomy 8 and del(20q), but deletions involving chromosomes 12, 13, 14, and 17 are also seen. It is important to note that a recurrent genetic abnormality that implicates a different disease should *not* be seen in aCML. Examples include *BCR*::*ABL1,* rearrangements of *PDGFRA, PDGFRB, FGFR1, JAK2, FLT3,* and *ABL1,* and rearrangements of *KMT2A*.

JAK2 mutations are very uncommon and should prompt consideration of an MPN.[1,72,73] Similarly, the detection of a *CSF3R* mutation should prompt strong consideration of chronic neutrophilic leukemia. Recurrent mutations in genes reported in confirmed cases of aCML include *SETBP1, ETNK1*,[74-76] *ASXL1, TET2,* and *NRAS;* in most cases, there is >1 mutation.[67] The majority of *SETBP1* missense mutations in aCML are reported to occur between codons 858 and 871 and are gain-of-function; they co-occur frequently with mutations in *ASXL1* and *EZH2*. Co-mutation of *SETBP1* and *SRSF2* has also been reported. Whenever a *SRSF2* mutation is detected in a case of aCML, it is not found in association with *TET2* mutation. *EZH2* co-mutated with *ASXL1* or *RUNX1* can also be observed.

Clinical Course

Most patients seem to fare poorly, with an overall median survival of 11 to 25 months. Age older than 65 years, female sex, WBC counts greater than 50 × 10^9/L, severe anemia, and thrombocytopenia are generally considered unfavorable prognostic features.[77] Patients who

receive bone marrow transplants may have an improved outcome. In 15% to 40% of patients, aCML evolves to AML, whereas the remainder succumb to bone marrow failure. In addition, mutations in *ASXL1, SETBP1,* and *TET2* genes have been associated with a more aggressive disease.[7,8]

Differential Diagnosis

Chronic Myelomonocytic Leukemia

The major distinguishing features between CMML and aCML are the percentage of monocytes in the blood (≥10% in CMML and <10% in aCML) and the extreme granulocytic dysplasia seen in most cases of aCML. Differences in the morphologic findings, underlying genetic alterations and overall median survival, argue that CMML and aCML are biologically separate entities. However, in clinical practice, occasional cases arise in which the distinction cannot be made with any degree of confidence. In such instances, denoting the two different differential diagnostic possibilities and perhaps assessing how the morphology plays out over time may help further clarify.

Chronic Myeloid Leukemia (CML), *BCR*::*ABL1* Positive

aCML (despite the unfortunate similar terminology) is easily distinguished from CML, *BCR*::*ABL1* positive, because the latter, by definition, harbors the Ph chromosome and/or *BCR*::*ABL1* fusion gene, which are not present in aCML. Appropriate cytogenetic or molecular genetic studies should always be performed when either diagnosis is suspected. Morphology can usually readily distinguish between these two disorders. Granulocytic dysplasia is essentially absent in the chronic phase of CML but prominent in aCML.

Basophilia may be present in both diseases, but it is usually less than 2% of the PB cells in aCML and greater than 2% in CML. Nevertheless, the accelerated phase of CML may be difficult to distinguish from aCML because dysplasia becomes more noticeable when CML progresses beyond the chronic phase. Cytogenetic/molecular genetic studies to exclude the *BCR*::*ABL1* fusion gene facilitate the correct diagnosis.

Myeloproliferative Neoplasms, *BCR*::*ABL1* Negative (Polycythemia Vera, Primary Myelofibrosis, Essential Thrombocythemia)

Cases of MPN, particularly those in accelerated phase and postpolycythemic or post–essential thrombocythemic myelofibrosis, may simulate aCML. A previous history of MPN, the presence of classical MPN-associated features in the bone marrow, and MPN-associated mutations (*JAK2, CALR,* or *MPL*) argue against a diagnosis of aCML.[1,3] Conversely, a diagnosis of aCML is supported by the presence of *SETBP1* or *EZH2* mutations.[79] The presence of a *CSF3R* mutation is very uncommon in aCML and should prompt careful morphologic review for an alternative diagnosis of chronic neutrophilic leukemia or other myeloid neoplasm.

Myelodysplastic Syndrome

Although the dysplasia observed in aCML is similar to that in MDS, the leukocytosis observed in aCML would not be expected in MDS. Rarely, an MDS case can transform to “secondary” aCML during the course of disease, a phenomenon that may be associated with the acquisition of novel gene mutations.[80]

Prognosis and Prognostic Factors

The limited number of cases reported in the literature precludes any definitive statement about disease outcome, but most patients seem to fare poorly, with an overall median survival of 11 to 25 months.[65,67] Age older than 65 years, WBC counts greater than 50 × 10^9/L, severe anemia, and thrombocytopenia are generally considered unfavorable prognostic features. Patients who receive bone marrow transplants may have an improved outcome. In 15% to 40% of patients, aCML evolves to AML, whereas the remainder succumb to bone marrow failure.[67-69]

Myelodysplastic/Myeloproliferative Neoplasm With *Sf3b1* Mutation and Thrombocytosis (MDS/MPN-*SF3B1*-T)

It has been learned that a distinct subset of cases previously categorized as MDS/MPN with ring sideroblasts and thrombocytosis (platelets ≥450 × 10^9/L) frequently shows mutations in *SF3B1* and that these are highly correlated with the presence of ring sideroblasts. Based on these findings, the ICC recognizes MDS/MPN with *SF3B1* mutation and thrombocytosis (MDS/MPN- *SF3B1*-T) as a distinct diagnostic clinicopathologic entity.[1,3,81-84] The diagnostic criteria for this entity are shown in **Box 48-7**.

Definition

MDS/MPN-*SF3B1*-T is a clonal hematopoietic stem cell disorder characterized by thrombocytosis and ring sideroblasts in the presence of an *SF3B1* mutation.

Box 48-7 Diagnostic Criteria for Myelodysplastic/Myeloproliferative Neoplasm With *SF3B1* Mutation and Thrombocytosis (MDS/MPN-*SF3B1*-T)

- Thrombocytosis, with platelet count ≥450 × 10^9/L
- Anemia (threshold same as for myelodysplastic syndrome)—(Hb <13 g/dL [males], <12 g/dL [females])
- Blasts <1% in blood and <5% in bone marrow
- Presence of *SF3B1* mutation (variant allele frequency ≥10%), isolated or associated with abnormal cytogenetics and/or other myeloid neoplasm associated mutations
- No history of recent cytotoxic or growth factor therapy that could explain the myelodysplastic/myeloproliferative features
- No *BCR*::*ABL1* or genetic abnormalities of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions; no t(3;3)(q21.3;q26.2), inv(3)(q21.3q26.2), or del(5q)*
- No history of myeloproliferative neoplasm, myelodysplastic syndrome, or other myelodysplastic/myeloproliferative neoplasm

* In a case that otherwise meets the diagnostic criteria for myelodysplastic syndrome with del(5q).

Synonyms

Refractory anemia with ring sideroblasts associated with marked thrombocytosis; myelodysplastic/myeloproliferative neoplasm with

SF3B1 mutation and thrombocytosis (WHO 5th edition 2022, Khoury 2022)[13]

Epidemiology

The incidence of MDS/MPN-*SF3B1*-T is unknown, but of myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis, not otherwise specified (MDS/MPN-RS-T, NOS) appears to represent the vast majority of cases. A median age of 74 years at the time of diagnosis has been reported, which is higher than that in MPNs such as essential thrombocythemia, with a slight female prevalence.

Etiology

The etiology is unknown.

Clinical Findings

Patients may present with symptoms related to the refractory anemia, which is often severe, or to excessive thrombocytosis, with bleeding or thrombosis; in many, the symptoms are related to both abnormalities. Splenomegaly has been reported in about 40% cases, and hepatomegaly may also occur.

Morphology

Blood

The WBC count is usually normal to modestly elevated, and there are no circulating blasts, or if present, they represent less than 1% of PB leukocytes.[82] Macrocytic or normocytic anemia is present, and the red blood cells often show a dimorphic pattern (**Fig. 48-12A**).

Dysplasia is lacking in the neutrophils (**Fig. 48-12B**). Platelets, by definition, are at least 450 × 10^9/L and may show clumping on the PB smear (**Fig. 48-12B**).

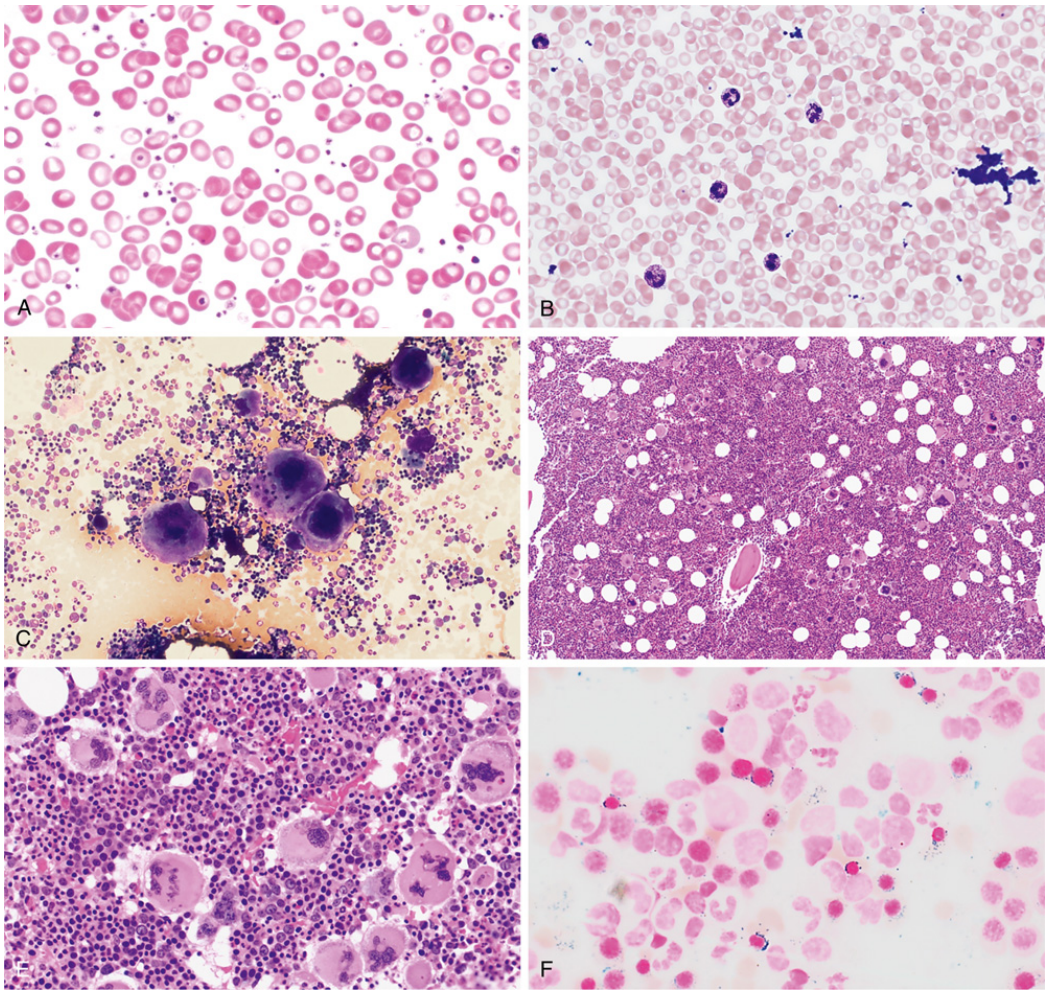

FIGURE 48-12 Peripheral blood and bone marrow features in myelodysplastic/myeloproliferative neoplasm with *SF3B1* mutation and thrombocytosis (A–F).A, Peripheral blood smear from an 83-year-old man with severe anemia and thrombocytosis of 1048 × 10^9/L shows abnormal macrocytic hypochromic red cells and a marked increase in platelets, showing anisocytosis. **B,** Peripheral blood smear showing lack of neutrophil dysplasia and marked platelet

clumping in the setting of marked thrombocytosis. **C,** Bone marrow aspirate smear demonstrates maturing trilineage hematopoiesis with markedly enlarged megakaryocytes with hyperlobulation with similar morphologic features to those seen in essential thrombocythemia. **D** and **E,** Bone marrow core biopsy shows a hypercellular bone marrow with marked erythroid and megakaryocytic proliferation and megakaryocytes with hyperlobulation and "staghorn-like" nuclei, mimicking essential thrombocythemia. **F,** The majority of sideroblasts are ring sideroblasts.

Bone Marrow

The bone marrow biopsy and aspirate smears are hypercellular and shows increased erythropoiesis often with megaloblastoid features and megakaryopoiesis (**Fig. 48-12C–E**). The megakaryocytic morphology is distinctive with many enlarged, hyperlobulated, and/or hyperchromatic forms morphologically similar to those seen in ET or primary myelofibrosis (PMF) (**Fig. 48-12D** and **E**). Dysplastic-appearing megakaryocytes are unusual and, if present, warrant consideration of an alternative diagnosis such as MDS. Erythropoiesis usually predominates and may be dysplastic, a feature that can best be appreciated in aspirate smears. Though in most cases at least 15% of the erythroid precursors are ring sideroblasts, in the presence of an *SF3B1* mutation (≥10% VAF), the identification of ring sideroblasts is no longer required for the

diagnosis (**Fig. 48-12F**). Blasts represent less than 5% of nucleated cells.

Immunophenotype

There are no specific immunophenotypic features reported.

Cytogenetics and Genetics

No karyotypic abnormality has been specifically associated with this disease, and the overwhelming majority show a normal karyotype. Nearly 50% of patients have the *JAK2* V617F mutation, and a smaller number (<10%) have mutated *MPL* W515K/L or a classic *CALR* mutation.[85-87] By definition, these cases harbor an *SF3B1* mutation, and most also show a co-mutation status with a *JAK2* mutation, which supports this diagnosis.[3,87,88]

Differential Diagnosis

Myelodysplastic Syndrome With *SF3B1* Mutation

In the uncommon instance of MDS-*SF3B1* with thrombocytosis, the morphologic features of the megakaryocytes should be of utility in discriminating these entities. In MDS/MPN-*SF3B1*-T, the megakaryocytes typically resemble those seen in ET or PMF and are not dysplastic as would be expected in MDS-RS. In one study of MDS, *SF3B1* mutated, a significantly higher prevalence of *JAK2* and *MPL* mutations was observed compared with *SF3B1*-unmutated MDS. Though the authors reported that these patients did not fulfill diagnostic criteria for a diagnosis of MDS/MPN-RS-T, it was noted that a significantly higher platelet count was found in patients with *SF3B1*-mutated MDS carrying either *JAK2* or *MPL* mutation

compared with those who were co-wild type (P < 0.001).[88] This finding supports consideration of a diagnostic continuum between the two *SF3B1* mutated entities, particularly because cases that initially present as MDS-*SF3B1* but later, upon acquisition of *JAK2* V617F mutation, progress to resemble MDS/MPN-*SF3B1*-T have been documented.[89]

Myeloproliferative Neoplasm With *SF3B1* Mutation

In MPN, *SF3B1* is mutated in approximately 10% of patients with PMF and 3% to 5% with PV or ET.[90,91] It is important for pathologists to recognize that a minor subset of classic *BCR*::*ABL1*-negative MPNs may harbor this mutation and that ring sideroblasts may also be seen in a subset of cases either at disease presentation or with progression.[91,92] Given that mutations in *JAK2/CALR/MPL* are highly prevalent in MPN, in the rare cases of MPN that harbor a concomitant *SF3B1* mutation, the distinction from MDS/MPN-*SF3B1*-T may be challenging. In the study by Boiocchi et al., the presence of an *SF3B1* mutation in a myeloproliferative neoplasm was not associated with myelodysplastic evolution/progression.[91] Therefore, the absence of a dysplastic component argues in favor of MPN. In addition, the absence or low percentage of ring sideroblasts (<15%) supports a diagnosis of a classic MPN.[92] The presence of anemia, often macrocytic and associated with marrow erythroid predominance in MDS/MPN-*SF3B1*-T, would also argue against a diagnosis of ET with ring sideroblasts.

Prognosis and Prognostic Factors

In general, MDS/MPN-*SF3B1*-T shows an overall better median survival than MDS/MPN-RS-T, NOS (6.9 vs. 3.3 years, P = 0.003,

respectively).[93] *JAK2* mutations are also independent factors for better prognosis. It is important to note that patients with MDS/MPN-RS-T do not fare as well as those with ET, who may have a near-normal life span if appropriately managed.[93] Thus, the distinction between these disorders is important from clinical, biological, and prognostic points of view.

Myelodysplastic/Myeloproliferative Neoplasm With Ring Sideroblasts and Thrombocytosis, Not Otherwise Specified (MDS/MPN-RS-T, NOS)

There are less frequent cases of MDS/MPN with thrombocytosis and >15% ring sideroblasts that lack a *SF3B1* mutation. In such cases, the ICC determines that designation as MDS/MPN-RS-T, NOS is appropriate. The diagnostic criteria for this entity are shown in **Box 48-8**. Both thrombocytosis and anemia must be present at the time of initial diagnosis. In addition, the presence of anemia that is thought to be related to the hematologic malignancy argues against classification as ET with ring sideroblasts. The clinical and morphologic features are apparently similar to MDS/MPN-T-*SF3B1,* although at least 15% ring sideroblasts are required. In terms of prognosis, in a multivariate analysis, age older than 80 years at diagnosis, *SF3B1* wild type, and *JAK2* wild type were independent factors of a worse prognosis.[93] Also, an *SF3B1* wild-type profile is more common in males (23.1%) than in females (5.1%), and mean ring sideroblast counts are lower than in *SF3B1* mutated cases (38% vs. 55%).[93]

Differential Diagnosis

Myeloproliferative Neoplasm With Ring Sideroblasts; *SF3B1* Mutation Negative

In the uncommon scenario of an MPN with ring sideroblasts, the percentage of ring sideroblasts is expected to be low (<15%), and dysplasia would be absent.

Box 48-8 Diagnostic Criteria for Myelodysplastic/Myeloproliferative Neoplasm With Ring Sideroblasts and Thrombocytosis, Not Otherwise Specified (MDS/MPN-RS-T, NOS)

- Thrombocytosis, with platelet count ≥450 × 10^9/L
- Anemia associated with erythroid-lineage dysplasia, with or without multilineage dysplasia, and ≥15% ring sideroblasts
- Blasts <1% in blood and <5% in bone marrow
- Presence of clonality: demonstration of a clonal cytogenetic abnormality and/or somatic mutation(s). In their absence, no history of recent cytotoxic or growth factor therapy that could explain the myelodysplastic/myeloproliferative features
- Absence of *SF3B1* mutation; no *BCR*::*ABL1* or genetic abnormalities of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions; no t(3;3)(q21.3;q26.2), inv(3)(q21.3q26.2), or del(5q)*
- No history of myeloproliferative neoplasm, myelodysplastic syndrome, or other myelodysplastic/myeloproliferative neoplasm

* In a case that otherwise meets the diagnostic criteria for myelodysplastic syndrome with del(5q).

Myelodysplastic/Myeloproliferative Neoplasm, Not Otherwise Specified (MDS/MPN, NOS)

When patients exhibit features that do not easily fit into any existing subcategory of the MDS/MPN disease types or any other myeloid malignancy, subclassification as MDS/MPN, NOS, is justified.[1,94,95] However, the term NOS should *only* be used when the appropriate clinical, morphologic, immunophenotypic, and genetic studies have been performed to determine that the disease truly does not fit a well-defined category. This subcategory is essentially a diagnosis of exclusion, as reflected in the diagnostic criteria (**Box 48-9**).

In MDS/MPN, NOS, by definition, cases must satisfy criteria for both MDS and MPN, (truly an overlap syndrome), and must not meet criteria for any other MDS/MPN subtype or myeloid malignancy (**Box 48-9**). As expected, the finding of a *BCR*::*ABL1* fusion gene or rearrangements of *PDGFRA, PDGFRB, FGFR1, JAK2, FLT3,* or *ABL1* excludes the diagnosis of MDS/MPN, NOS. In addition, the presence of a mutation in *JAK2, CALR,* or *MPL* should raise the possibility of an alternative diagnosis of MPN.

The designation of "NOS" must not be applied to patients with MPNs who have dyspoietic features/cytopenias as a consequence of therapy or disease progression. This category should not be used for advanced-stage MPN or triple-negative MPN cases. If the patient has received any growth factor or cytotoxic therapy before the initial

diagnostic evaluation, additional clinical and laboratory studies are essential to prove that the dyspoietic or proliferative features are not related to the therapy.

Myelodysplastic/Myeloproliferative Neoplasm With Isolated Isochromosome (17q) (MDS/MPM With i[17q]; ICC Provisional Subentity)

MDS/MPN with i(17q) is a provisional subentity under the category of MDS/MPN, NOS.[3,4] These neoplasms are rare and are often associated with hybrid myelodysplastic/myeloproliferative features, hence their inclusion in this overarching category.

Box 48-9 Diagnostic Criteria for Myelodysplastic/Myeloproliferative Neoplasm, Not Otherwise Specified (MDS/MPN, NOS)

- Myeloid neoplasm with mixed myeloproliferative and myelodysplastic features, not meeting the International Consensus Classification (ICC) criteria for any other myelodysplastic/myeloproliferative neoplasm, myelodysplastic syndrome, or myeloproliferative neoplasm*
- Cytopenia (thresholds same as for myelodysplastic syndrome [MDS])†—anemia, Hb <13 g/dL [males], <12 g/dL [females]; neutropenia, absolute neutrophil count $<1.8 \times 10^9$/L; thrombocytopenia, platelets $<150 \times 10^9$/L)
- Blasts <20% of the cells in blood and bone marrow

- A platelet count of ≥450 × 10^9/L and/or a white blood cell count of ≥13 × 10^9/L
- Presence of clonality: demonstration of a clonal cytogenetic abnormality and/or somatic mutation(s). If clonality cannot be determined, the findings have persisted and all other causes (e.g., history of cytotoxic or growth factor therapy or other primary causes that could explain the myelodysplastic/myeloproliferative features) have been excluded.
- No *BCR*::*ABL1* or genetic abnormalities of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions; absence of t(3;3)(q21.3;q26.2), inv(3)(q21.3q26.2),[‡] or del(5q)[§]

---

[*] Myeloproliferative neoplasms, in particular those in accelerated phase and/or post–polycythemia vera or post–essential thrombocythemia myelofibrotic stage, may simulate MDS/MPN, NOS. A history of MPN and/or the presence of MPN-associated mutations (in *JAK2, CALR,* or *MPL*), particularly if associated with a high variant allele frequency, tend to exclude a diagnosis of MDS/MPN, NOS. The presence of hypereosinophilia would favor a diagnosis of chronic eosinophilic leukemia, not otherwise specified.

[‡] In a case that otherwise meets criteria for myelodysplastic syndrome, not otherwise specified.

[†] Based on International Consensus Group Conference, Vienna, 2018 (Valent et al., 2019).

§ In a case that otherwise meets the diagnostic criteria for myelodysplastic syndrome with isolated del(5q).

The diagnostic criteria are outlined in **Box 48-10**.

Definition

MDS/MPN with i(17q) is a clonal hematopoietic stem cell disorder with features of both a myelodysplastic and myeloproliferative neoplasm with a characteristic cytogenetic abnormality of isochromosome 17q and/or one additional chromosomal abnormality, excluding an abnormality of chromosome 7 (del 7q/monosomy 7).

Epidemiology

The incidence of this disease is unknown.

Etiology

The etiology is unknown.

Clinical Findings

The average age at presentation is 67 years with an approximately equal male-to-female distribution. Splenomegaly is quite frequent at approximately 70%.

Box 48-10 Diagnostic Criteria for Myelodysplastic/Myeloproliferative Neoplasm With Isolated Isochromosome (17q) [MDS/MPN with i(17q)]*

Fulfills the general criteria for a diagnosis of MDS/MPN, NOS

- Leukocytosis of ≥13 × 10^9/L
- Cytopenia (thresholds same as for myelodysplastic syndrome [MDS])[†]—(anemia, Hb <13 g/dL [males], <12 g/dL [females]; neutropenia, absolute neutrophil count <1.8 × 10^9/L; thrombocytopenia, platelets <150 × 10^9/L)
- Blasts <20% of the cells in blood and bone marrow
- Dysgranulopoiesis with non-segmented or Pseudo–Pelger-Huët neutrophils
- An i(17q), either isolated or occurring with one other additional abnormality (other than −7/del[7q])
- No *BCR*::*ABL1* or genetic abnormalities of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions
- Absence of myeloproliferative neoplasm–associated mutations (*JAK2, CALR,* and *MPL*)[‡]
- No history of recent cytotoxic or growth factor therapy that could explain the MDS/MPN features

---

[*] MDS/MPN with i(17q) is considered a provisional subentity of MDS/MPN, NOS.

[‡] Presence of MPN features in the bone marrow and/or MPN-associated mutations (in *JAK2, CALR,* or *MPL*) suggests progression of an underlying MPN that was not diagnosed and should be excluded; conversely, in the appropriate clinical context, presence of mutations, particularly co-existent

mutation in *SRSF2* and *SETBP1* genes, further supports this diagnosis.

† Based on International Consensus Group Conference, Vienna, 2018 (Valent et al., 2019).

Morphology

Blood

At initial presentation, leukocytosis and anemia are prevalent. By definition, there is no monocytosis (≤10% monocytes). In one multiinstitutional study, 79% of the patients had leukocytosis (WBC ≥13 × 10^9/L) and 25% had thrombocytosis (platelet count ≥450 × 10^9/L). Every patient had anemia (Hgb <12 g/dL). Neutrophils typically show distinctive and prevalent dysplastic features characterized strongly by nonlobated or hypolobated pseudo–Pelger-Huët nuclei and cytoplasmic hypogranulation (**Fig. 48-13A** and **B**). There are less than 20% blasts in the PB.

Bone Marrow

The bone marrow is typically hypercellular with abundant pseudo–Pelger-Huët neutrophils in bone marrow, as seen in the PB.[96-98] Dysplastic-appearing megakaryocytes may be seen in some cases, characterized by micromegakaryocytes, hypolobated/monolobated forms, and forms with separate distinct nuclear lobes. Ring sideroblasts are uncommon (**Fig. 48-13C–F**). There are less than 20% blasts in the bone marrow. Bone marrow fibrosis may be seen but is not more prevalent than in cases of MDS/MPN, NOS without i(17q).

Genetics

By definition, these cases harbor an isochromosome 17q resulting in a *TP53* gene deletion. In a study evaluating molecular genetic alterations using NGS technology, this provisional entity was noted to have an increased frequency of mutations in *SRSF2, SETBP1,* and *ASXL1* genes. Double mutations involving *SRSF2* and *SETBP1* were seen in 44% of cases.[99] The genetic signatures show overlap with aCML and somewhat with CMML—supporting some similarities in their pathogenesis.

One interesting finding is that, although there is a *TP53* deletion by cytogenetics, an additional *TP53* mutation was not significantly detected in these neoplasms. Thus, these cases appear to be characterized, for the most part, by a monoallelic *TP53* mutation state; the remaining *TP53* allele is wild type. FISH and array comparative genomic hybridization/single nucleotide polymorphism (aCGH/SNP) studies performed on a subset of cases confirmed the heterozygous nature of the *TP53* deletion and absence of copy-neutral loss of heterozygosity, confirming monoallelic *TP53* alteration.[99]

Prognosis

The prognosis for patients with chronic myeloid neoplasms with i(17q) is adverse, with an overall median survival of approximately 11 months.[99] There is a high rate of transformation to AML.[98,100,101] Given these findings, it is thought to be important to annotate these cases specifically, such that an ongoing prospective evaluation of these cases may be performed.

Differential Diagnosis

The differential diagnosis, based on clinical, morphology, and laboratory features, could include CMML, MPN, aCML, and MDS/MPN, NOS. Overall, perhaps one of the initial discriminating clues to a homogenous entity is presence of the i(17q) genetic abnormality. There is genetic overlap with the aforementioned disorders (CMML with mutations in *TET2, SRSF2, ASXL1,* or *CBL* and aCML with mutations in *ASXL1, SETBP1,* and *SRSF2*). CMML should, however, show monocytosis by definition, and although it may occur, striking dysgranulopoiesis is relatively uncommon. Presence of MPN features in the bone marrow and/or MPN-associated mutations (in *JAK2, CALR,* or *MPL*) suggests progression of an underlying MPN that was not diagnosed and should be excluded. Though there is definite overlap with aCML, which arguably serves the primary diagnostic challenge, the high frequency of co-mutations in *SRSF2* and *SETBP1* genes observed in one study may help in supporting a diagnosis MDS/MPN with i(17q).[99] In summary, at the present time, the finding of i(17q) in the otherwise appropriate clinical and morphologic context would favor subclassification as the provisional subentity of MDS/MPN with i(17q).

Acknowledgments

The authors graciously appreciate and acknowledge the work of the prior authors, Drs. James Vardiman and Elizabeth Hyjek, that has inspired and contributed significantly to this updated chapter.

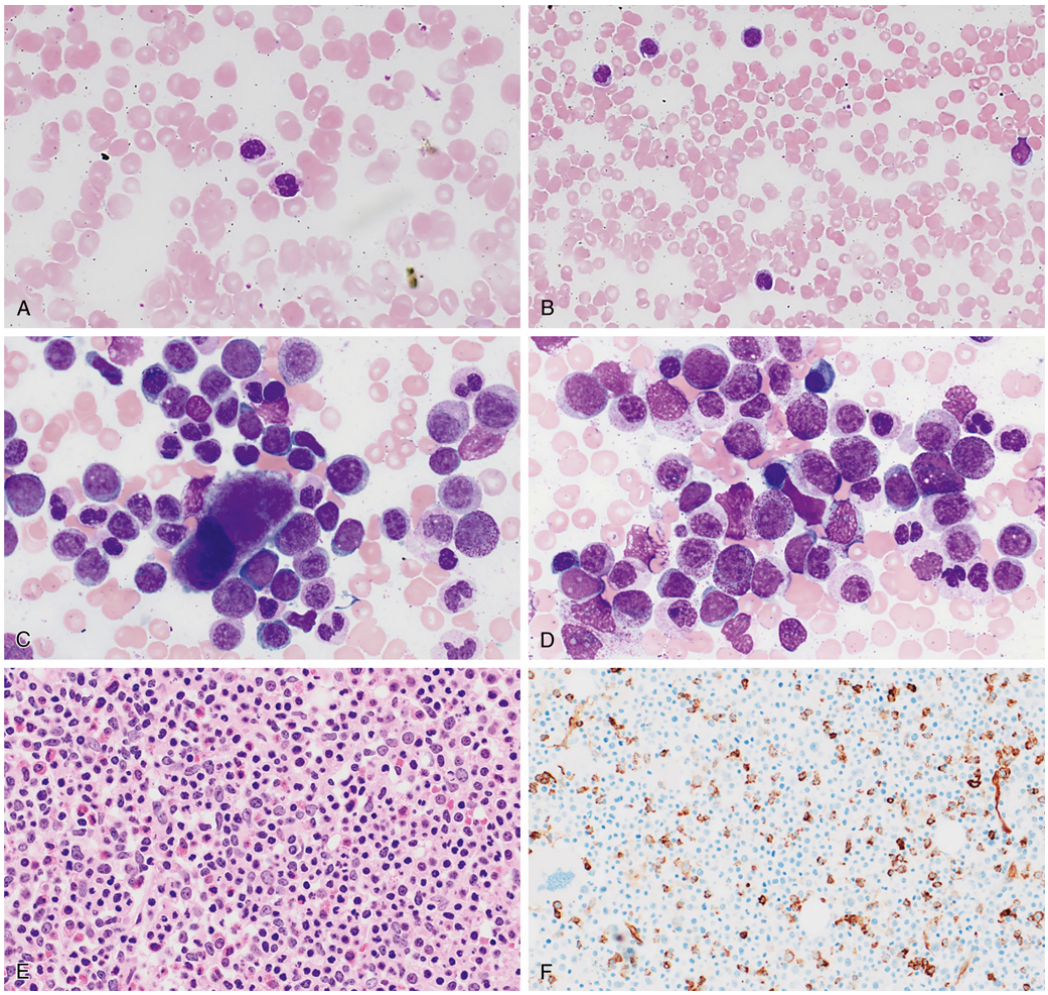

FIGURE 48-13 Peripheral blood and bone marrow features in the International Consensus Classification (ICC) provisional subentity myelodysplastic/myeloproliferative neoplasm with isochromosome (17q) (A–F).A, Dysplastic granulocytes showing Pelger-Huet-like nuclei with condensed chromatin and hypogranular cytoplasm are common. **B,** Many patients will have absolute monocytosis with abnormal appearing yet mature monocytes. In

the illustrated case, a circulating blast can be seen on the *right-hand side* of the photomicrograph. **C** and **D,** Aspirate smears are hypercellular with a granulocytic proliferation and marked dysplasia and dysmegakaryopoiesis. **E,** Bone marrow core biopsy shows granulocytic proliferation; even the dysplasia can be appreciated on the section. **F,** Immunohistochemical staining for CD34 demonstrates an increase in CD34-positive blasts.

Pearls and Pitfalls

- All the MDS/MPN entities and their subtypes are *BCR*::*ABL1*-negative myeloid neoplasms. Their blast count is less than 20%.
- A diagnosis of MDS/MPN requires, in almost all instances, both proliferative (i.e. cytosis/es) and dysplastic/cytopenic features being present at disease presentation.
- CMML should be subclassified as either the myelodysplastic or myeloproliferative subtype, depending on the WBC count at presentation.
- Distinguishing monoblasts, promonocytes, and abnormal monocytes is essential for the diagnosis of CMML and its (lower) blast count versus AML.
- Reactive monocytosis is much more common than CMML.

- Rearrangement of *KMT2A* or an *NPM1* mutation should prompt rereview of a case thought to be CMML (to exclude AML).
- Cases of CMML are enriched for mutations in the *TET2, ASXL1,* and *SRSF2* genes.
- If there is no significant myeloid dysplasia, no clonal myeloid-related cytogenetic abnormality, no significant increase in blasts, and monocytosis is persistent and unexplained, in the setting of a molecular genetic abnormality, a premalignant condition associated with monocytosis could be considered.
- CMUS is a CMML precursor condition that can be diagnosed in patients with persistent monocytosis (monocytes ≥10% and $\geq 0.5 \times 10^9$/L of the WBC), presence of myeloid neoplasm-associated mutation(s) and absence of bone marrow morphologic findings of CMML.
- In cases of CMUS in which a cytopenia(s) is also present, the terminology of CCMUS is suggested.
- Eosinophilia in what looks like an MDS/MPN should always prompt the consideration of rearrangement of *PDGFRA, PDGFRB, FGFR1, JAK2, FLT3,* and *ABL1*.
- aCML is a rare entity characterized by neutrophilic leukocytosis associated with dysgranulopoiesis and circulating immature neutrophilic precursors. Abnormal nuclear chromatin clumping of neutrophils is also a feature.
- It is important to enumerate monocytes and eosinophils carefully because they are a key feature in distinguishing aCML from CMML.

- Eosinophils should not be prominent in aCML and should account for <10% and <1.5 × 10^9/L of the leukocytes.
- In MDS/MPN, NOS, by definition, cases must satisfy criteria for both MDS and MPN (truly an overlap syndrome), and must not meet criteria for any other MDS/MPN subtype or myeloid malignancy. In particular, such cases should not represent accelerated phase and/or post–PV or post–ET myelofibrotic stages. A history of MPN and/or the presence of MPN-associated mutations (in *JAK2, CALR,* or *MPL*), particularly if associated with a high VAF, should call into question a diagnosis of MDS/MPN, NOS.
- MDS/MPN with i(17q) is a provisional subentity under the category of MDS/MPN, NOS. Neutrophils typically show distinctive and prevalent dysplastic features characterized strongly by pseudo–Pelger-Huët nuclei and cytoplasmic hypogranulation. Molecular genetic overlap with CMML with mutations in *TET2, SRSF2, ASXL1,* and aCML with mutations in *ASXL1, SETBP1,* and *SRSF2* can be seen.

Chapter 49: Mastocytosis

Alexandar Tzankov, Karl Sotlar, Peter Valent, Hans-Peter Horny, and Tracy I. George

OUTLINE

Definition

Synonyms and Related Terms

General Aspects

Epidemiology and Etiology

Postulated Cell of Origin and Normal Counterpart

Genetics and Molecular Findings

Cytologic and Histologic Diagnosis

- **Cytology**
- **Histology**
- **Immunophenotype**
- **Histopathologic Findings**

Differential Diagnosis

- **Mast Cell Activation Syndrome**

Classification

Cutaneous Mastocytosis

Indolent Systemic Mastocytosis

Systemic Mastocytosis With an Associated Myeloid/Hematologic Neoplasm

Aggressive Systemic Mastocytosis

Mast Cell Leukemia

Mast Cell Sarcoma

Extracutaneous Mastocytoma

The most common subtype of cutaneous mastocytosis (CM), termed at that time *urticaria pigmentosa* (UP), was first described in the 19th century, a decade before mast cells (MCs) were defined by Paul Ehrlich as metachromatic cells of the connective tissue.[1,2] In 1949, the first histologic proof of involvement of visceral organs by mastocytosis was reported.[3] Since that time, many terms have been introduced to describe mastocytosis. These terms are now obsolete and should no longer be used (e.g., generalized mastocytosis, malignant mastocytosis, aleukemic or subacute basophilic mastocytoma or leukemia, UP with bone involvement or with systemic lesions, and eosinophilic fibrohistiocytic lesion of the bone marrow [BM]).[4-10] Various classification systems for mastocytosis have been proposed and finally established.[11-15] During the past 3 decades, major discoveries have led to both a better understanding of the pathophysiologic processes involved in the evolution of

mastocytosis and clarification of the nosology of this group of diseases. Using an animal model, Kitamura and coworkers[16] demonstrated that MCs are of hematopoietic origin. Later, the hematopoietic origin of MCs was confirmed for other species, including humans.[17-22] Evidence has also accumulated from extensive histologic and cytologic studies that the BM and the skin are the preferred sites of involvement in human mastocytosis, that MCs share some histochemical properties with other cells of the myeloid lineage, and that systemic mastocytosis (SM) may be associated with myeloid (non-MC) neoplasms.[23-26] It has also been demonstrated that human MCs differentiate under the influence of stem cell factor, also known as MC growth factor, a cytokine that binds to the KIT (CD117) tyrosine kinase receptor, also known as KIT-ligand, and that MCs arise from a BM-derived CD34-positive, KIT-positive progenitor cell.[19-22] As far as the diagnosis of mastocytosis is concerned, immunohistochemical markers such as tryptase, CD2, CD25, CD30, and KIT/CD117 are well established.[27-32] Finally, recurrent activating somatic point mutations in certain regions of the *KIT* proto-oncogene, especially *KIT* D816V, have been detected in MCs in tissue infiltrates of SM.[33-35] Altogether, these findings clearly indicate that SM is a BM-derived myeloid neoplasm exhibiting an unusually broad clinical and morphologic spectrum of disorders. A consensus classification of mastocytosis was initially proposed at the Year 2000 Working Conference on Mastocytosis in Vienna, Austria.[35] This consensus classification was adopted by the World Health Organization (WHO) classification in 2001 and in 2008 and refined in 2017 in the revised WHO classification.[36-38] In 2022, both the International Consensus Classification (ICC) and the

proposed WHO 5th edition further modified diagnostic criteria for SM.[12,13] These updates are essentially based on clinical studies and the outcomes of the Year 2020 Working Conference on Mastocytosis in Vienna, Austria.[39]

Definition

Mastocytosis is characterized by an abnormal accumulation of MCs in various organ systems. Two main categories of disease exist: a) CM, which involves only the skin; and b) SM, which by definition involves at least one extracutaneous organ, most commonly the BM. CM and SM include an array of heterogeneous disorders that nevertheless constitute a discrete group among the hematologic diseases (**Box 49-1**). These diseases range from benign and regressing solitary mastocytomas in children to aggressive MC leukemias, predominantly in adults. Hence, whereas it is probable that all variants of SM and most adult patients with CM have true neoplasms, it is not clear whether this also holds true for all children with CM, as approximately 40% show spontaneous regression of symptoms at puberty, and not all CM cases present with *KIT* mutations.

Synonyms and Related Terms

None.

General Aspects

Mastocytosis can occur at any age and presents with an unusually broad spectrum of symptoms. Among these, disseminated red-brown

macules and papules that become red and swollen on rubbing or scratching (Darier's sign) are almost pathognomonic of maculopapular CM (MPCM; formerly termed UP, which is the most common variant of CM. However, the same skin lesions are also seen frequently in indolent SM (ISM).[40] On the other hand, absence of skin lesions does not exclude the presence of SM. In contrast to patients with CM, most patients with SM have elevated levels of serum tryptase, which is produced almost exclusively by normal and neoplastic MCs and can be used to monitor patients with confirmed SM.[41]

Box 49-1 International Consensus Classification (ICC) and Proposed World Health Organization (WHO) 5th Edition Classification of Mastocytosis

Data from Arber DA, Orazi A, Hasserjian RP, et al. International Consensus Classification of myeloid neoplasms and acute leukemias: integrating morphologic, clinical, and genomic data. *Blood*. 2022;140:1200; Khoury JD, Solary E, Abla O, et al. The 5th edition of the World Health Organization classification of haematolymphoid tumours: myeloid and histiocytic/dendritic neoplasms. *Leukemia*. 2022;36:1703; Valent P, Akin C, Hartmann K, et al. Updated diagnostic criteria and classification of mast cell disorders: a consensus proposal. *HemaSphere*. 2021;5:e646.

Elevated serum tryptase is thus an important sign of an underlying SM. However, elevated serum tryptase can also be detected in individuals with a recently described autosomal dominant genetic condition, hereditary alpha tryptasemia (HαT), which is characterized by increased copies of the *TPSAB1* gene encoding for α-tryptase and affects 4% to 6% of the general population.[42,43] Interestingly, HαT is two to three times more common in patients with SM than in healthy individuals, and *Hymenoptera* venom hypersensitivity reactions and severe anaphylaxis is by far more frequent in patients with mastocytosis with HαT than in those without HαT.[44,45] An important practical aspect in that consideration is noted in the proposed WHO 5th edition classification,[13] which prescribes serum tryptase to be adjusted in HαT, following the proposal of the 2020 consensus group.[39] Although the optimal adjustment remains to be defined, it is suggested to divide the basal tryptase level by 1 plus the extra copy numbers of the *TPSAB1* gene, e.g. when the tryptase level is 30 and two extra copies of the gene are found in a patient with HαT, the HαT-corrected tryptase level is 10 (30/3 = 10) and thus not a minor SM criterion.[39]

Patients with advanced SM, defined as MC leukemia (MCL), aggressive SM (ASM), or SM with an associated myeloid/hematologic neoplasm (AMN/AHN) may have marked (palpable) hepatosplenomegaly and generalized lymphadenopathy, ascites, weight loss, and/or signs of malabsorption; rarely, they may also have larger (i.e., ≥2 cm) osteolyses.[14,36-39] A significant number of patients with SM, many of them with ASM, have an AHN; most of the AMNs have been proven to be of the same clonal origin as the

neoplastic MCs, though those of the lymphoid were not.[46,47] For this reason, the ICC 2022 is not as restrictive and only includes SM with an AMN for this category.[12] A definitive diagnosis of mastocytosis can be made only based on a histopathologic analysis of tissue specimens (particularly BM), including immunostaining with antibodies against tryptase, KIT/CD117, CD25, and CD30; it should not be based on clinical and serologic findings alone.[14,29-32,39,48-50]

Epidemiology and Etiology

Mastocytosis is a rare disease, especially the systemic variants. MCL is one of the rarest forms of human leukemia, with a few hundred well-documented cases reported to date.[51-56] The exact incidence of mastocytosis is unknown, and similar to other rare hematologic disorders, the apparent incidence may vary according to the experience of clinicians and pathologists.[57] There is a slight male predominance. Disease onset generally occurs either during the first year of life, when most cases of CM develop, or during adulthood, with a peak in the 5th and 6th decades, accounting for most cases of SM. In many cases with ISM without skin involvement, the disease may not be detected or is detected by chance (occult SM). In many of these cases, (isolated) BM mastocytosis (BMM) may be diagnosed. Whereas BMM has previously been described as a provisional subset of ISM,[14] BMM is recognized in the proposed WHO 5th edition[13] as a distinct variant of SM based on its unique clinical features and a more favorable prognosis than that of ISM.[39,58] BMM is considered a subtype of ISM in the ICC 2022.[12]

The cause of mastocytosis is unknown. Very rare familial cases have been reported, which particularly applies to a distinct

morphologic subvariant of SM characterized by early onset, diffuse cutaneous involvement, specific phenotype with absent to low expression of CD2 and CD25, consistent high expression of CD30, a female predominance of 4:1, childhood disease onset in >90% and wild-type *KIT* or *KIT* variant mutations; this subvariant is termed SM with well-differentiated mast cells (WDSM).[59]

Postulated Cell of Origin and Normal Counterpart

Normal MCs are phenotypically more closely related to myeloid cells than to lymphoid cells. However, in SM, MCs often display lymphoid marker antigens, such as CD2, CD25, or CD30.[14,29-32,39,48-50] Nevertheless, SM, irrespective of subtype, is considered a myeloid neoplasm that evolves from neoplastic CD34-positive hematopoietic stem cells, which give rise to MC-committed precursor cells and neoplastic MCs.[60] The cell of origin in CM is also considered to be an MC-committed stem and precursor cell, although the exact source organ from which these cells invade the skin remains uncertain. Pointing toward the myeloid origin of MCs in CM, at least in a group of mainly adult patients with CM, BM involvement is demonstrable, even if the full criteria to diagnose SM are not fulfilled.[40]

There is considerable morphologic overlap between basophils and MCs, but these are distinctly different cell types.[17,18] Both are the only myeloid cells that contain intracytoplasmic metachromatic granules and are therefore usually recognizable on certain histochemical stains, such as Giemsa and toluidine blue. Mature MCs do not circulate and are found predominantly in the perivascular connective tissue. The differentiation and maturation of MCs usually

occur at extramedullary sites.[17,18,61,62] In contrast to MCs, basophils differentiate in the BM, circulate as mature leukocytes, and finally migrate into the perivascular tissues. Also, basophils have an estimated life span of only a few days, whereas MCs exhibit a life span of several months to years.[61,63] Although mature MCs and basophils can be differentiated from each other on BM smears, neoplastic metachromatic cells (including metachromatic blasts or immature mast cells) may exhibit marked atypia, making it almost impossible to clearly distinguish between basophils and neoplastic MCs by morphologic examination. The metachromatic granules of basophils, unlike those of MCs, are water soluble so that basophils, whether normal, reactive, or neoplastic, are undetectable by the pathologist in routinely processed tissue specimens. However, basophil-specific monoclonal antibodies, namely 2D7 and BB1, are applicable to formalin-fixed, paraffin-embedded tissues, and basophils do not express KIT/CD117.[64,65] A summary of the most important phenotypic differences between MCs and basophils is provided in **Table 49-1**.

Genetics and Molecular Findings

Various mutations of the *KIT* proto-oncogene and other genetic defects have been shown to result in stem cell factor–independent activation of KIT and KIT-downstream signaling pathways.[66] One of these point mutations, *KIT* D816V, was first described by Furitsu and associates in HMC-1 cells derived from a patient with MCL.[33] Most of the mutations described in patients with mastocytosis cluster in exons 11 and 17. The most frequently detected mutation is *KIT* D816V. In rare cases, mutations in other exons have been described

(**Table 49-2**).[33,34,67-77] The vast majority of mutations described in mastocytosis are somatic. In contrast, germline mutations are extremely rare and have been described in only a few cases of familial mastocytosis.[59,69,72,75,78-80] The K509I *KIT* variant deserves special attention, as it may be either germline or somatic, and in addition to increasing the sensitivity of the affected cells to stem cell factor, the resulting mutant KIT protein it is sensitive to imatinib.[70,81]

Table 49-1

Major Phenotypic Features Distinguishing Between Mast Cells and Basophils*

Marker	Mast Cells	Basophils
Metachromasia/Giemsa	++/+++	–[†]
CAE	++/+++	–
Tryptase	+++	–/+/+[‡]
Chymase	++/+	–
CD2	++[§]	–
CD9	++	++[¶]
CD25	+++[§]	+[¶]
CD30	+/++[§]	–
CD34	–	–
CD45	+++	+++
CD68	+++	–
CD117 (KIT)	+++/++	–
2D7	–	++/+
BB1	–	++/+

+++, Strong expression (strong staining of virtually all cells); ++, moderate expression (moderate staining of most cells); +, weak

expression (weak staining of a minority of cells); –, no specific staining of cells.

CAE, Naphthol AS-D chloroacetate esterase.

* Histologic distinction in routinely processed (formalin-fixed) tissues, including bone marrow trephine biopsy specimens. Phenotypic expression by flow cytometry is present for the following markers used in routine clinical practice: CD2, CD9, CD25, CD34, CD45, and CD117. CD9 is expressed in normal basophils by flow cytometry, and CD25 is dimly expressed in normal basophils by flow cytometry.

† Unlike in smears, basophils contain no metachromatic granules in sections.

‡ Expression is inconsistent and occurs only in neoplastic states (e.g., in chronic myeloid leukemia).

§ Expressed in mast cells only in neoplastic states (mastocytosis); CD2 expression by flow cytometry on mast cells is more sensitive than immunohistochemistry.

¶ CD9 is expressed in normal basophils by flow cytometry, and CD25 is dimly expressed in normal basophils by flow cytometry.

The respective *KIT* mutation may be largely confined to MCs and their precursor cells or may be detectable in multiple lineages. Mutational involvement of multiple hematopoietic cell lineages is usually associated with smoldering SM (SSM) or more aggressive (advanced) forms of SM (SM-AMN, ASM, MCL).[74,82] In these patients, an increased variant allele frequency (VAF) of the mutant *KIT* and, notably, *KIT* D816V mutation with VAF ≥10% in BM cells

or peripheral blood leukocytes may be detected; in the context of SSM, a VAF ≥10% qualifies as a B finding (diagnostic sign of SSM) according to the proposed WHO 5th edition[13,39] but is not included as such in the ICC 2022.[12] Not only *KIT* D816V but also other *KIT* codon 816 mutations (D816Y, D816H, and D816F, the last representing a combination of D816V and D816Y mutations) and mutations in other codons of *KIT* may act as gain-of-function mutations.[34,67,68,75] This is important, as in the ICC 2022, the proposed WHO 5th edition, and the consensus group proposal, any type of activating mutation in *KIT* qualifies as a minor diagnostic criterion of SM.[12,13,39] It is also worth noting that the non-D816V codon 816 mutations are significantly more frequent in CM than in SM, with D816F being detected only in CM so far.[18,75]

Table 49-2

Adapted from Valent P, Akin C, Sperr WR, et al. New insights into the pathogenesis of mastocytosis: emerging concepts in diagnosis and therapy. *Ann Rev Pathol.* 2023;18:361.[18]

KIT mutations can be detected in more than 90% of all patients with SM and in about 40% of those with CM. Therefore, all SM cases and most pediatric cases with *KIT* mutated (persistent) CM can be regarded as hematopoietic neoplasms.[18,30,74] As mentioned, any activating *KIT* mutation has been promoted as a minor diagnostic criterion for SM in both the ICC 2022 and the proposed WHO 5th edition classifications of mastocytosis (Boxes **49-2** and **49-3**).[12,13,36-39] Various techniques have been used to detect *KIT* mutations, including restriction fragment length polymorphism

analysis, direct sequencing, peptide nucleic acid–mediated polymerase chain reaction (PCR) clamping and melting point analysis, various allele-specific PCR techniques, and digital droplet PCR (ddPCR).[18,34,67,68,83-87] The sensitivity for the detection of *KIT* mutations is increased when MCs are enriched by cell sorting or by microdissection, which is usually not needed when applying ddPCR. A remarkable aspect is that, although MCs are usually not detectable in the bloodstream, *KIT* D816V can be detected in peripheral blood leukocytes with highly sensitive assays in most patients with SM.[34,67,68,88] Recommendations for *KIT* mutation analysis in MC neoplasms and approaches to both diagnosis and follow-up of patients with SM have been published.[34,67,68]

Detection of *KIT* mutations has prime importance in mastocytosis in general and in SM in particular. This is because such mutations (1) represent a minor diagnostic criterion required by the current classification systems[12,13,39]; (2) are associated with aberrant expression of CD25, CD2, and probably CD30[89]; (3) represent a decisive tool for pathologists to select cases to be specifically tested for myeloid/lymphoid neoplasms with eosinophilia (M/LN-Eo) and tyrosine kinase gene fusions, which are *KIT* wild type[90]; (4) are—if assessed in a quantitative manner—of significant prognostic value; and (5) are a major predictive marker of various targeted drug sensitivities, including the highly selective D816V KIT variant inhibitor avapritinib,[91,92] the less selective tyrosine kinase inhibitor with activity against D816V KIT midostaurin,[93] and imatinib in cases associated with “noncanonical” *KIT* mutations and even rare wild-type instances.[94] Finally, the degree to which non-MC lineages are affected by *KIT* mutations, which is roughly reflected by the

respective VAFs, appears to substantially determine the clinical course of mastocytosis; the more MC lineage-restricted progenitors are affected, the more indolent form of disease the patients suffers from, and vice versa, the more undifferentiated progenitor cells and the more hematopoietic lineages are affected, the more aggressive the disease is.[95,96] An exception is SSM, in which multiple lineages and progenitors are affected but the prognosis is excellent and progression to an advanced SM is rather uncommon.[14,39] As mentioned, *KIT* D816V mutation with a VAF ≥10% is regarded as a B finding in the proposed WHO 5th edition classification,[13] which would upgrade ISM to SSM (when a second B finding is also detected) in respective rare instances. Thus, D816 hot-spot and—if wild-type—complete *KIT* gene sequencing should be considered mandatory in SM.

It should be noted that ISM and, to a degree, SSM are typically unimutational diseases, with most cases harboring only a *KIT* mutation.[82,95,96] In contrast, advanced SMs (SM-AMN and ASM) are multimutational diseases, with almost all cases displaying additional non-*KIT* mutations, often more than one.[96-98] Identification of poor-risk non-*KIT* variants (e.g., mutations in *ASXL1, CBL, DNMT3A, EZH2, NRAS, RUNX1,* and *SRSF2*) aids in the risk stratification of patients and should be actively sought in the latter SM subtypes.[95,97-103]

Box 49-2 Systemic Mastocytosis: Diagnostic Criteria

ICC, International Consensus Classification; *SM-AMN,* systemic mastocytosis with associated myeloid neoplasm; *WHO,* World Health Organization.

Major Criterion

Multifocal dense infiltrates of tryptase-positive and/or CD117-positive mast cells (≥15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organ(s)*

Minor Criteria

In bone marrow biopsy or in section of other extracutaneous organs, >25% of mast cells are spindle shaped or have an atypical immature morphology

Mast cells in bone marrow, peripheral blood, or other extracutaneous organs express CD2, CD25, and/or CD30, in addition to mast cell markers

KIT D816V mutation or other activating *KIT* mutation detected in bone marrow, peripheral blood, or other extracutaneous organs†

Elevated serum tryptase level persistently >20 ng/mL.‡ In cases of SM-AMN, an elevated tryptase does not count as a systemic mastocytosis minor criterion

The diagnosis of systemic mastocytosis can be established when the major criterion is present according to the ICC 2022,[12] the major and one minor criteria are present according to the proposed WHO 5th edition and the 2020 Working

Conference on Mast Cell Disorders,[13,39] or three minor criteria are fulfilled[12-14,39]

---

* In the absence of a *KIT* mutation, particularly in cases with eosinophilia, the presence of tyrosine kinase gene fusions associated with myeloid/lymphoid neoplasm with eosinophilia must be excluded according to the ICC 2022.

‡ According to the proposed WHO 5th edition, mast cell tryptase level should be adjusted in the case of hereditary alpha-tryptasemia.[13,39]

† To avoid "false negative" results, use of a high sensitivity polymerase chain reaction assay for detection of *KIT* D816V mutation is recommended. If negative, exclusion of *KIT* mutation variants is strongly recommended in suspected systemic mastocytosis.

Cytologic and Histologic Diagnosis

Cytology

The diagnosis of mastocytosis based on BM smears alone is difficult because of the small number of aspirated MCs, even in patients whose BM trephine biopsy specimens reveal marked MC infiltration. The aspiration of MCs is hampered by the marked reticulin and/or collagen fibrosis accompanying the compact tissue infiltrates and by the fact that infiltration is predominantly focal. Nevertheless, the BM aspirate is of great importance in the diagnosis, staging, and grading of SM. Normally, MCs account for <0.1% of all nucleated BM cells.[29] Larger numbers of MCs are only occasionally seen in smears (Figs. **49-1** and **49-2**). In most cases of ISM/SSM, the number of MCs in BM smears is only slightly elevated and ranges from 0.1% to a maximum of about 2%.[104] In most patients with ASM, the percentage of MCs in BM smears ranges between 1% and 5%. In a small proportion of cases, however, the MC count in BM smears is markedly elevated and correlates with the prognosis and final diagnosis; indeed, ≥20% MCs on aspirates (proposed WHO 5th edition) or ≥20% immature MCs (ICC 2022) define MCL (in instances fulfilling diagnostic criteria of SM).[12,13] In patients with ASM in which MCs account for up to 19%, the prognosis is poor, as many of them progress to MCL. The percentage of MCs in BM smears in ASM correlate with prognosis. In those with ASM with a BM MC count of 5% to 19%, the diagnosis ASM in transformation (ASM-t) applies.[39,105]

Box 49-3 **B and C Findings**

VAF, Variant allele frequency.

B Findings[14,39]

High mast cell burden, ≥30% of infiltration of bone marrow cellularity by mast cell aggregates (assessed on bone marrow biopsy) and/or serum total tryptase ≥200 ng/mL[14,39]
and/or *KIT* D816V mutation with VAF ≥10% in bone marrow cells or peripheral blood leukocytes[39]
Cytopenia (not meeting criteria for C findings) or –cytosis; reactive causes are excluded, and criteria for other myeloid neoplasms are not met[14,39]
or
Signs of dysplasia or myeloproliferation in non–mast cell lineages, not meeting criteria for an associated hematologic neoplasm, with normal or only slightly abnormal blood counts[14,39]
Hepatomegaly without impairment of liver function or splenomegaly without features of hypersplenism, including thrombocytopenia, and/or lymphadenopathy (>1 cm size), on palpation or imaging

C Findings[14,39]

Bone marrow dysfunction caused by neoplastic mast cell infiltration, manifested by ≥1 cytopenia: absolute neutrophil count $<1.0 \times 10^9$/L, hemoglobin level <10 g/dL, and/or platelet count $<100 \times 10^9$/L
Hepatomegaly with impairment of liver function, ascites, and/or portal hypertension

Skeletal involvement, with large (≥2 cm) osteolytic lesions with or without pathologic fractures
Splenomegaly with hypersplenism
Malabsorption with weight loss caused by gastrointestinal tract mast cell infiltrates

The degree of MC atypia varies greatly and is most pronounced in MCL. In general, the following MC types can be recognized in BM smears in patients with SM: metachromatic blast (immature MC); atypical MC type I (spindle shaped); atypical MC type II (promastocyte); and typical mature tissue (well-differentiated) MC, defined as a well-granulated round cell with a round central nucleus.[14,39,105,106]

The following criteria define atypical MCs type I[106]:

1. Hypogranulation with reduction of metachromatic granules. Markedly hypogranulated MCs may even appear nonmetachromatic on staining with basic dyes such as Giemsa and toluidine blue and may only very weakly stain for tryptase on immunohistochemistry.
2. Oval and eccentric nuclei.
3. Spindling. This is typically seen in SM but is occasionally seen in reactive states of MC hyperplasia as well.

If two or three of these criteria are fulfilled, the cells should be called atypical MCs type I.[106] If the MC nuclei are bilobed or polylobed, the cells are termed atypical MCs type II or promastocytes.[106]

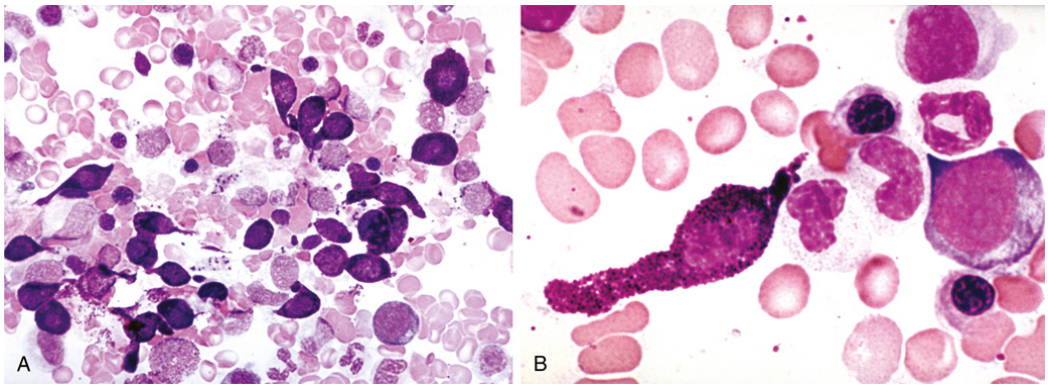

FIGURE 49-1 Indolent systemic mastocytosis: bone marrow smear.A, This case exhibits unusually large numbers of strongly metachromatic mast cells, which are round or spindle shaped and contain centrally located, slightly pleomorphic nuclei without prominent nucleoli. **B,** On higher magnification, note that the spindle-shaped mast cell is larger than the normal blood cell precursors.

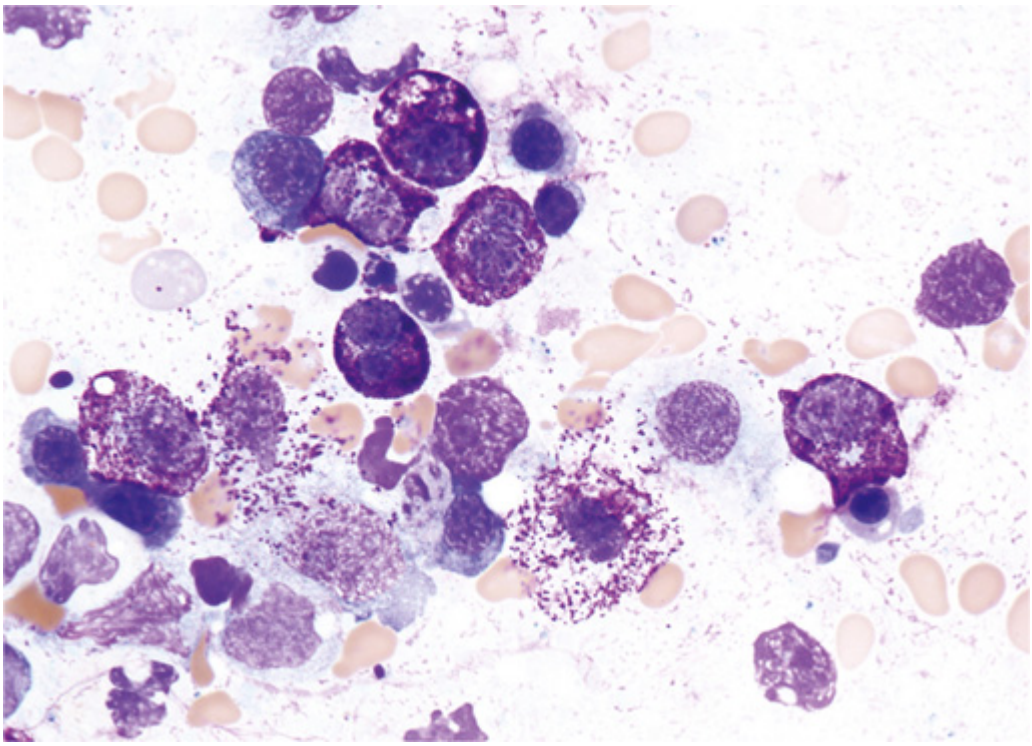

FIGURE 49-2 Aggressive systemic mastocytosis: bone marrow smear. In this case with a large number of mast cells, note that the mast cells contain fewer granules than those depicted in **Figure 49-1**.

The rare diagnosis of MCL can sometimes be suspected from blood smears in which circulating MCs are present. In these patients, circulating MCs usually exhibit varying degrees of atypia. MCs may be strongly metachromatic and easily identifiable, or they may be very atypical, with scanty metachromatic granules and, occasionally, a blast-like appearance (**Fig. 49-3**). A definitive diagnosis of MCL can be made when MCs constitute more than 20% of all nucleated cells in BM smears, though in the presence of suboptimal smears (dry tap), which is unfortunately often the case, diffuse, dense infiltration of atypical immature MCs is considered sufficient to

support the diagnosis of MCL in the ICC 2022.[12] In classical MCL, circulating MCs represent more than 10% of blood leukocytes (**Fig. 49-4**). If MCs constitute more than 20% of nucleated BM cells but less than 10% of leukocytes in the peripheral blood, an aleukemic MCL can be diagnosed.[13,14,36-38,39,105] Although the ICC 2022 does not use the term aleukemic MCL, MCL can be diagnosed in such cases based on 20% or more atypical, immature MC in the BM.[12]

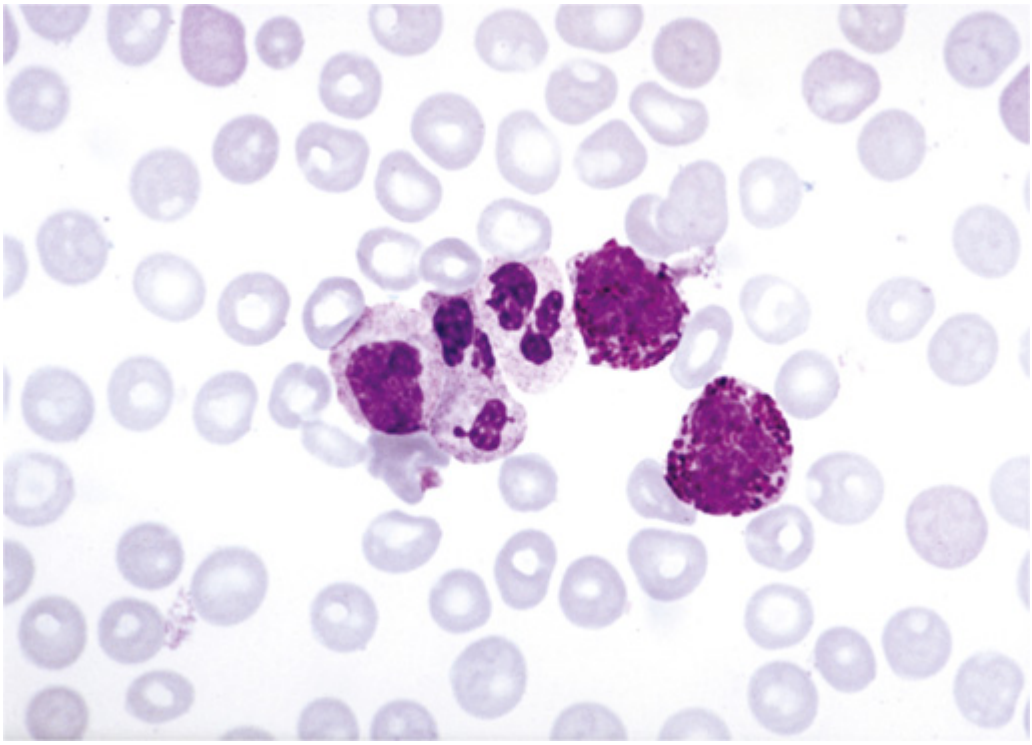

FIGURE 49-3 Myelomastocytic leukemia: blood smear. Two atypical cells with metachromatic granules are shown. It is not possible to determine the nature of these cells (mast cells or basophils) on the basis of morphology alone. Because bone marrow sections from this case showed a significant increase in tryptase-positive, CD117-positive mast cells (see **Fig. 49-14**), it can be assumed that these circulating cells are atypical mast cells.

Histology

Histologic investigation is imperative for the diagnosis, subtyping, and grading (confirmation of SM-induced organ damage) of mastocytosis.[36-38] Histologic evaluation of BM trephine biopsy

specimens taken from the iliac crest provides the definitive diagnosis of SM in most cases.[15,107] Noticeably, the biopsy may be taken at the exact site of SM involvement *(locus minoris resistentiae)*; thus, special attention should be paid to the specimen's ends, edges, and break lines. This investigation should always include immunohistochemistry with antibodies against tryptase, KIT/CD117, CD25, and CD30.[12,13] In addition, stains for detection or exclusion of an AMN, including CD34, should be applied in all cases. Staining for tryptase and KIT/CD117 not only enables MC numbers to be assessed easily and reliably but also facilitates the assessment of MC infiltration patterns in the BM, allowing the detection of compact MC infiltrates even if they are very small (**Figs. 49-5–49-7**). It is highly recommended to stain for both tryptase and KIT/CD117 so as not to miss or underestimate tryptase^{dim}-positive atypical MCs or overestimate KIT/CD117-positive non-MCs. Expression of CD25 and/or CD30 confirms the neoplastic state of an MC and enables the diagnosis of SM to be established in the setting of the other required criteria, given these are not expressed on normal or reactive MCs. CD2 expression also defines an atypical immunophenotype of MC[108] but is more easily detected by flow cytometry than by immunohistochemistry. CD30 has been promoted as a novel minor criterion of SM, being an aberrant marker regularly expressed on neoplastic MCs.[12,13,31,32,50] Especially in advanced SM, MCs often display strong cytoplasmic expression of CD30 (**Fig. 49-8**). However, CD30 expression is not specific for ASM or MCL but is also found in ISM and particularly WDSM, the latter usually lacking CD2 and CD25.[59]

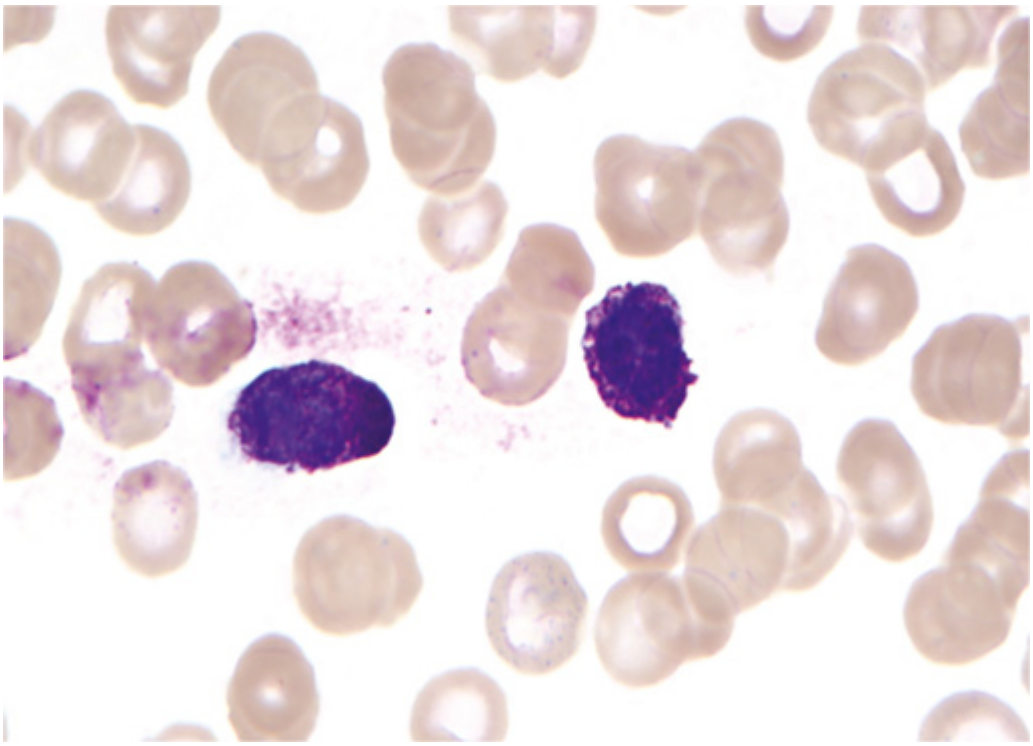

FIGURE 49-4 Mast cell leukemia: blood smear. Circulating pleomorphic mast cells with many metachromatic granules can be seen. Note the round nuclei, which distinguish these cells from basophils.

Four major types of BM infiltration patterns have been defined based on the number and localization of MCs[109]:

1. Focal, with disseminated or multifocal compact MC infiltrates. This is the most common pattern in ISM and SM-AMN/AHN.
2. Diffuse-interstitial, with an increase in loosely scattered MCs. The exclusive occurrence of a diffuse-interstitial pattern generally indicates the reactive state of MC hyperplasia, but it

may also be encountered in the BM of patients with CM or HαT.

3. Diffuse-compact, with complete effacement of preexisting BM. This type of infiltration pattern is usually seen in MCL, but it may also be encountered in advanced stages of SSM and ASM.

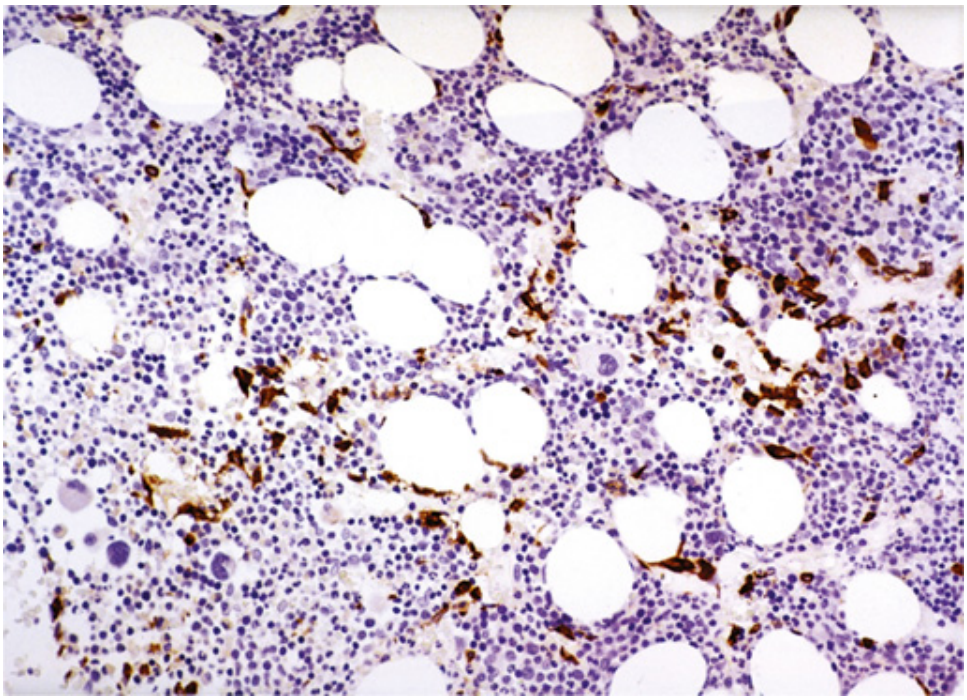

FIGURE 49-5 Bone marrow from a patient with cutaneous mastocytosis. Immunostaining for tryptase reveals an increase in loosely scattered mast cells within a slightly hypercellular bone marrow. Some small groups of mast cells can be seen, but there are no compact infiltrates. By definition, this is not indolent systemic mastocytosis. This case illustrates the diffuse infiltration pattern (interstitial subtype) that can be seen in reactive states (mast cell hyperplasia) and in systemic mastocytosis.

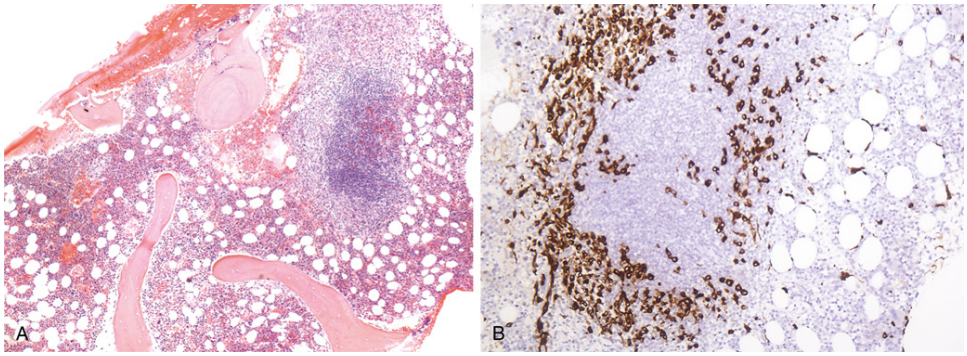

FIGURE 49-6 Indolent systemic mastocytosis: bone marrow findings.A, The marrow is slightly hypercellular and exhibits intact hematopoiesis and an aggregate of mast cells with admixed lymphocytes. **B,** The mast cells surrounding the lymphocytes show strong expression of tryptase. Note the spindle shape of most of the mast cells and the absence of increased mast cell numbers in the diffuse infiltrate (compare with **Fig. 49-5**). The patient has also mastocytosis in the skin.

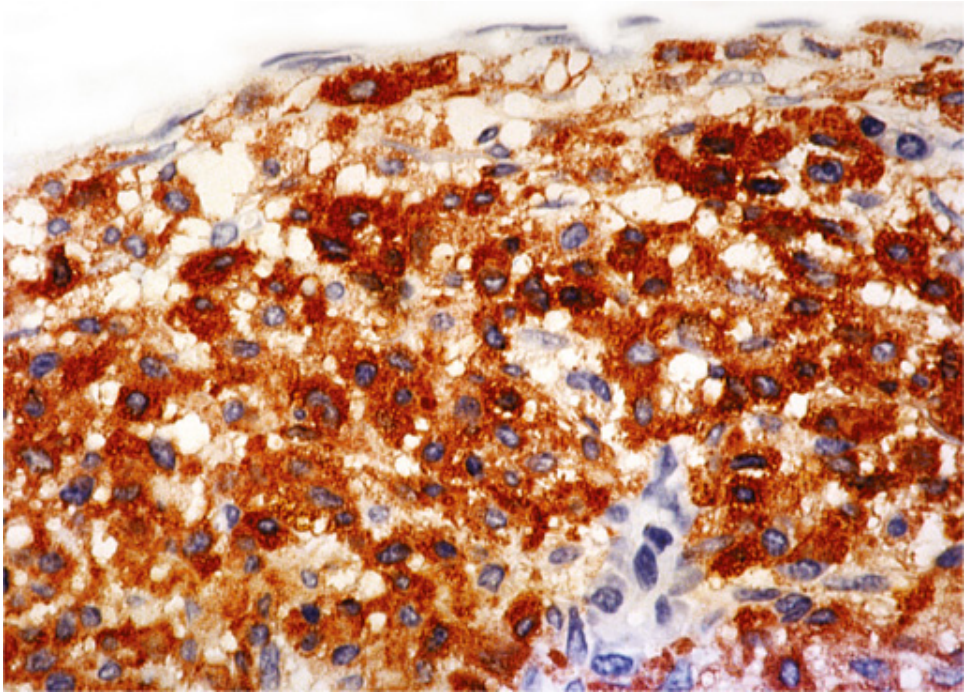

FIGURE 49-7 Mast cell leukemia: bone marrow findings. The diffuse-compact infiltration pattern on tryptase staining is found almost exclusively in mast cell leukemia (compare with Figs. **49-5** and **49-6**). The mast cells exhibit strong expression of tryptase, reflected in the typical granular cytoplasmic staining. Note the absence of spindling of mast cells and the subtotal depletion of fat cells and normal blood cell precursors.

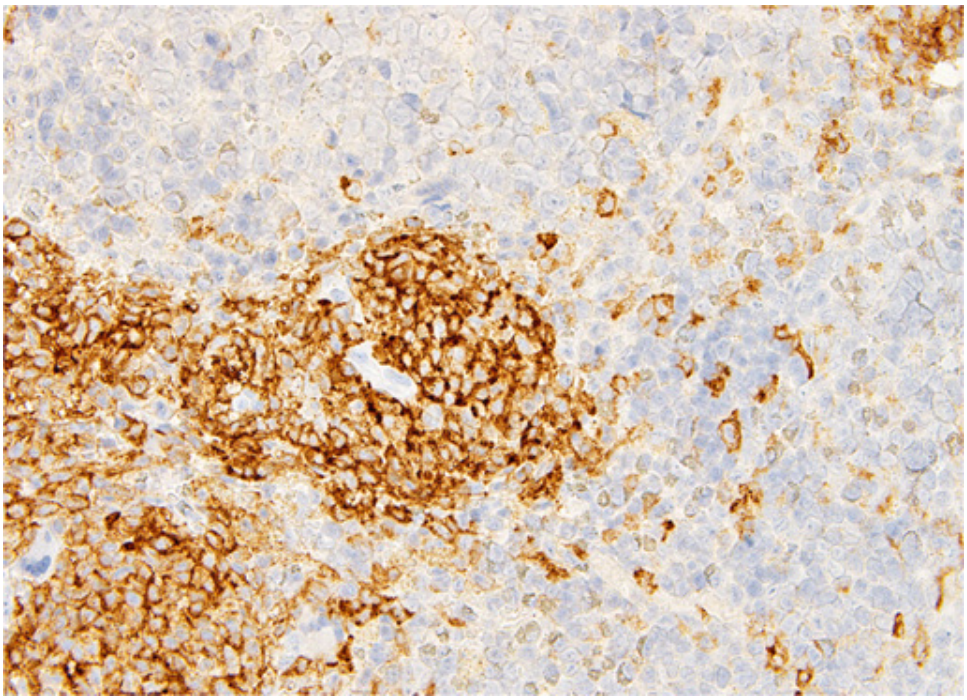

FIGURE 49-8 Aggressive systemic mastocytosis (same case as **Fig. 49-20**) positive for CD30 with a typical membrane-accentuated expression pattern.

4. Mixed (focal and diffuse-interstitial). This pattern is typically seen in ASM and MCL and is commonly associated with clinical signs of BM failure, but it also occurs in a subgroup of patients with SSM.

It has been shown by morphometry that the number of MCs in diffuse-interstitial infiltration patterns is usually significantly higher in cases of mastocytosis, irrespective of subtype, than in reactive states.[49] However, it cannot be overemphasized that the demonstration of at least one dense or compact MC infiltrate comprising ≥15 cells is the key finding for a definitive diagnosis of SM.[34] This holds true for the BM and for extramedullary organs such as the spleen, lymph nodes, and gastrointestinal (GI) tract.

Immunophenotype

Virtually all reactive and neoplastic MCs express tryptase, for which staining is granular and intracytoplasmic, and KIT/CD117, for which staining is usually annular and membrane associated (but can be also cytoplasmic) (**Fig. 49-9**).[48,49] An important exception is that SM involving the GI tract typically shows dim to occasionally negative expression of tryptase by immunohistochemistry.[110] Typically, the co-expression of tryptase and KIT enables MCs to be clearly distinguished from basophils. The basophils may produce small amounts of tryptase in neoplastic states, usually chronic myeloid leukemia (CML), but they are usually negative for KIT/CD117 (exception: immature basophil precursor cells).[111] Several studies have shown that neoplastic MCs in SM react with antibodies against CD2, CD25, and CD30, whereas normal and reactive MCs are usually negative for these markers.[30-33,50] In about 50% of ISM cases, MCs in BM infiltrates express CD2, although the membrane-associated reactivity is often relatively weak; in contrast, the surrounding or intermingled T cells are strongly positive for CD2.[108] CD25 staining produces a granular cytoplasmic and membrane-associated positive and clearly diagnostic result in almost all patients with SM. However, there are also cases in which SM cannot be diagnosed but MCs still express CD25. Examples are chronic inflammatory reactions, monoclonal MC activation syndromes (MCAS), M/LN-Eo,[90] and chronic eosinophilic leukemia (CEL). Because lymphoid cells expressing CD25 are rarely found in the normal or reactive BM, and because megakaryocytes, which are often dim CD25-positive, can clearly be distinguished from MCs, the BM is the ideal tissue to confirm or to exclude CD25 expression in

(atypical/neoplastic) MCs.[30] Identifying CD25-positive MCs is often difficult at extramedullary sites, especially in samples containing larger amounts of lymphocytes, such as mucosal layers, lymph nodes, and spleen. As mentioned, neoplastic MCs in SM often express CD30 in a moderate to strong granular cytoplasmic and occasionally membranous pattern.[31,32] MCs also may react with some of the routinely used macrophage-associated antibodies, especially those against CD68 and PG-M1/CD68r.[112,113] MCs, particularly neoplastic MCs, also express a variety of other antigens, such as CD4, CD13, CD33, CD43, CD45, CD56, CD123, vascular endothelial growth factor, and chymase, which is another highly specific but less sensitive MC-associated protease.[114-116] A summary of the markers relevant to the diagnosis of SM is provided in **Table 49-3**.

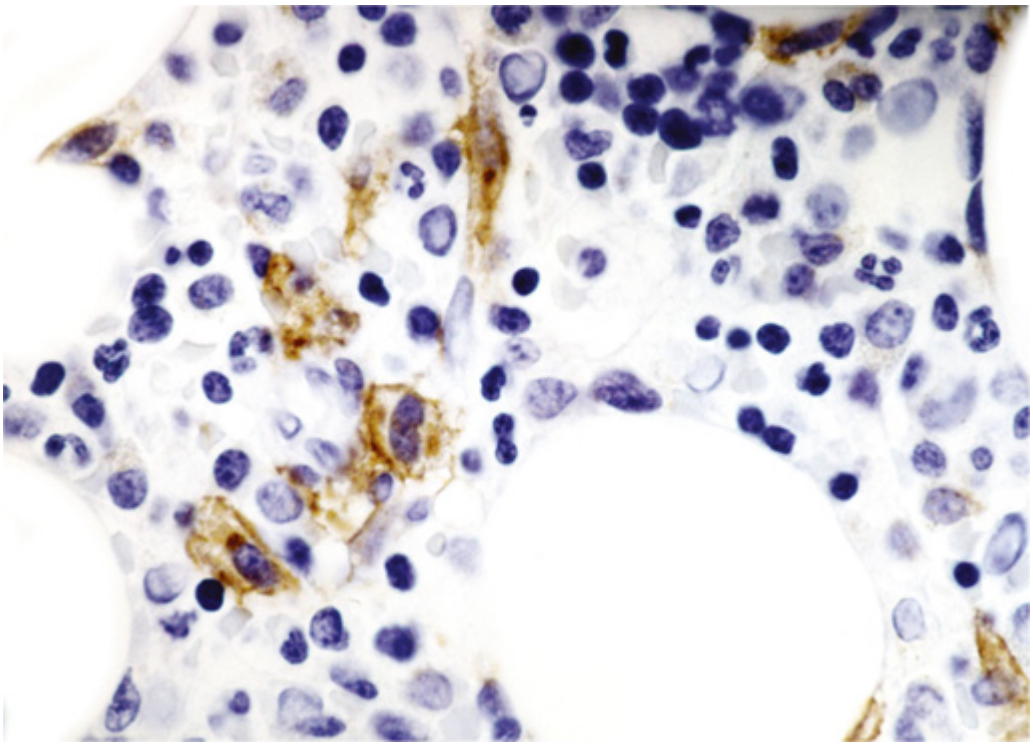

FIGURE 49-9 Indolent systemic mastocytosis: bone marrow findings. Slightly hypercellular marrow with a significant increase in mast cells that exhibit typical annular membrane-associated staining by an antibody against CD117.

In neoplastic states, it is necessary to phenotypically distinguish mastocytosis from myeloid leukemias exhibiting signs of MC differentiation but not fulfilling the diagnostic criteria of mastocytosis, including tryptase-positive acute myeloid leukemia (AML) and myelomastocytic leukemia (MML), but also from primary and secondary basophilic leukemias and accelerated CML with marked basophilia.[117] Discrimination among MCs, immature basophils and metachromatic blasts is hampered by the fact that, in contrast to normal or reactive MCs, atypical MCs may exhibit

irregularly contoured and sometimes bilobed nuclei and thus resemble monocytes or granulocytic cells.[109,111] A clear distinction among MCs and basophils and their neoplastic derivatives can be achieved by applying a limited panel of stains such as naphthol AS-D chloroacetate esterase (CAE), tryptase, KIT/CD117, and 2D7 or BB1. Normal and neoplastic MCs express CAE, tryptase, and KIT but only little, if any, 2D7 and BB1; basophils usually lack CAE and KIT but express 2D7 and BB1 and (when immature) may also express small amounts of tryptase, especially in CML.[104,111] MML is a myeloid neoplasm, defined by the presence of increased MCs (typically metachromatic blasts or immature MCs) and increased myeloblasts, not meeting criteria for SM-AMN/AHN (AML) or MCL.[105] MCs in MML comprise at least 10% of all nucleated BM or peripheral blood cells, and myeloblasts are usually >5%. In contrast to MCL and SM-AML, MML lacks MC aggregates, expression of CD25 (rare positive instances being described), and the *KIT* D816V mutation (while other *KIT* mutations can be found in a subset of cases).[118] MML often displays a complex karyotype. About half of patients meeting the definition of MML present with a history of a myeloid neoplasm with increased immature MCs upon progression, while others have a de novo presentation of disease resembling MDS, MPN, or AML.

Histopathologic Findings

The histopathologic findings commonly associated with tissue infiltration by mastocytosis in different organs are provided herein (**Box 49-4**).

Bone Marrow

Because the BM is involved in almost all cases of SM,[11,15,107,109] the definitive diagnosis is usually based on the histopathologic findings in trephine specimens taken from the iliac crest. The typical histopathologic picture is a multifocal or disseminated, usually perivascular and paratrabecular, granulomatous-appearing infiltrate of mixed cellularity. The cellular composition of these infiltrates varies greatly, but diagnostically, MCs are the most important component. They form cohesive groups of round, epithelioid, or spindle-shaped cells that may be located centrally or peripherally. Lymphoid aggregates adjacent to compact MC infiltrates are commonly seen in BM infiltrates of ISM/SSM but are rarely encountered in ASM and MCL. The reactive lymphocytic component may be so pronounced that a diagnosis of low-grade lymphoma may be suspected.[119] The fact that lymphoplasmacytic lymphoma and some cases of chronic lymphocytic leukemia are associated with increased numbers of reactive MCs may cause some diagnostic problems, yet MC clusters would not be observed.[120] There is almost always an increase in eosinophils, plasma cells, histiocytes, and fibroblast-like cells within or around tissue MC infiltrates of SM.

Table 49-3

Box 49-4 Histopathologic Findings Associated With Tissue Infiltrates of Mastocytosis*

Reticulin fibrosis
Neoangiogenesis
Collagen fibrosis
Osteosclerosis (bone marrow)
Eosinophilia
Lymphocytosis
Plasmacytosis

* Listed in decreasing order of frequency.

Compact tryptase and/or KIT/CD117-positive MC infiltrates are the histologic hallmark of mastocytosis, representing the major

diagnostic SM criterion that is sufficient for the diagnosis of SM according to the consensus group, the WHO, and the ICC 2022,[12,32,39] and contain a dense network of reticulin fibers. In long-standing SM, collagen fibrosis develops. Paratrabecular MC infiltrates almost always produce osteosclerosis, which is predominantly focal. Finally, prominent neoangiogenesis, with an increase in small blood vessels of the capillary type, is almost always seen in compact MC infiltrates.[121] The highly specific microarchitecture of such compact MC infiltrates is related to certain MC mediators, such as fibroblast growth factor, tryptase, chymase, vascular endothelial growth factor, chemokines, and interleukins.[121,122] The number and size of MC infiltrates vary greatly. Compared with ISM, SSM, and ASM usually exhibit more MC infiltrates, which are also larger and sometimes confluent. In SSM, a high MC burden, defined as >30% of infiltration of BM cellularity by MC aggregates, is a disease-related feature (B finding). Hematopoiesis is largely intact in most cases of ISM but is markedly reduced and often associated with clinical signs of BM failure (cytopenia) in ASM, MCL, and SM-AMN. Most cases of MCL can be easily recognized by the extreme hypercellularity of the marrow because of diffuse-compact infiltration, which leads to pronounced displacement of fat cells and normal hematopoiesis. There is usually only a slight to moderate increase in reticulin fibers. SM-AMN may represent a particular diagnostic challenge because small, compact MC infiltrates may be obscured by the associated hematologic malignant neoplasm and can be detected only in tryptase immunostains.[123] Indeed, it has been shown for AML t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1* that 12.5% of patients had SM when

marrow biopsies were stained for tryptase, and 10% to 15% of patients with CMML are expected to also have SM, the prognosis in both instances being worse when associated to SM.[55,124-127] Thus, it is recommended to perform tryptase immunostaining in all cases of AML t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1* and all cases of CMML to capture SM-AMN/AHN.

Spleen

Normal and reactive splenic tissue (except the fibrous capsule) is virtually devoid of MCs; therefore, an increase in metachromatic cells, especially cohesive groups or larger infiltrates of MCs, is almost pathognomonic of mastocytosis.[128-130] The degree of infiltration varies greatly; it may be pronounced and associated with marked splenomegaly (>1000 g). MC infiltrates may be either found predominantly in the red pulp or in the white pulp, but they are more often evenly distributed between the two compartments (**Fig. 49-10**). As in the BM, MC infiltrates often have a granulomatous appearance; as such, a histiocytic/dendritic or reticulum cell tumor may initially be suspected, especially if the MCs are atypical and metachromatic granules are absent. The correct diagnosis is easily missed in cases of SM-AMN/AHN and may be almost impossible without immunostaining for tryptase. Application of ancillary methods (immunohistochemistry, sequencing) leads to the diagnosis of SM in such cases, even if other organs are not affected. Isolated splenic mastocytosis is a rare diagnosis, although a few cases of mastocytosis with predominant involvement of the spleen associated with splenomegaly and clinical signs of hypersplenism have been reported.[131] In such instances, the degree of BM involvement may be

very small and can be assessed definitively only by immunohistochemistry. This underlines the fact that, in mastocytosis, as in other malignant neoplasms, the extent of infiltration of one organ does not allow one to draw definitive conclusions about other tissues. As in the BM, MC infiltrates in the spleen are always accompanied by an increase in reticulin and, in later stages of the disease, collagen fibers. A reactive increase in eosinophils and plasma cells is often seen as well.

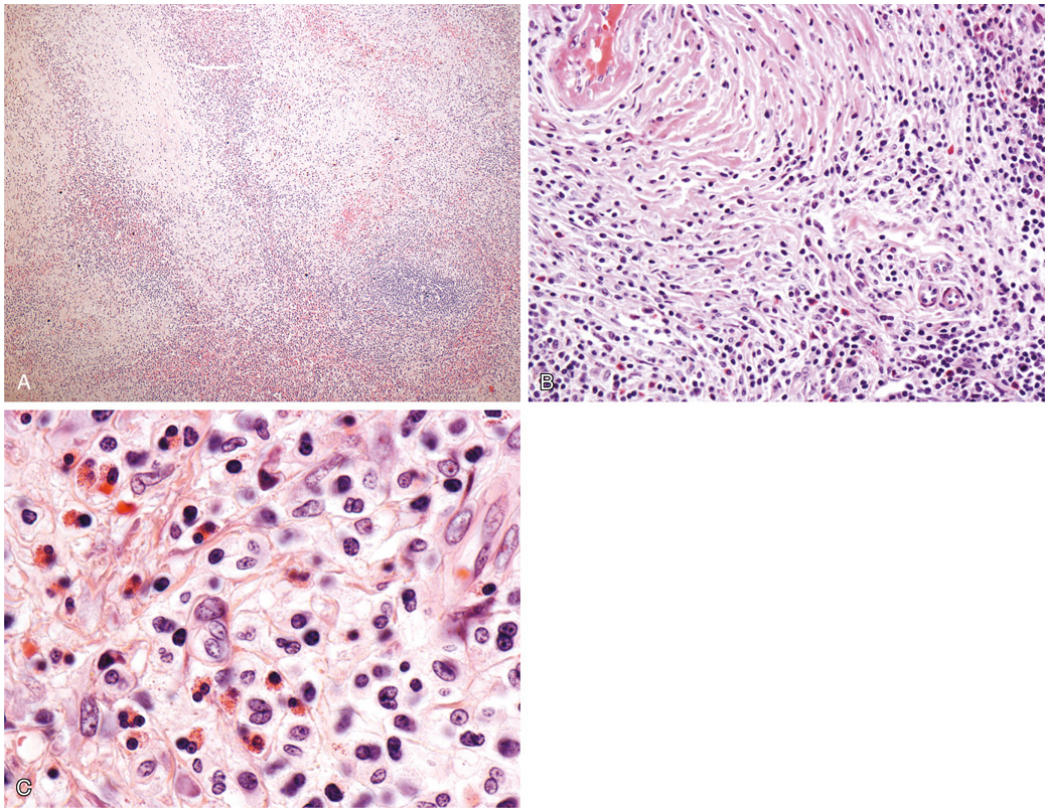

FIGURE 49-10 Spleen findings in systemic mastocytosis.A, The spleen shows patchy areas of fibrosis and mast cell aggregates in the red pulp and adjacent to the white pulp. **B,** Fibrotic areas show an infiltration of spindled and round mast cells with admixed eosinophils. **C,** Red pulp aggregates of round mast cells with abundant cytoplasm and admixed eosinophils are also present. The mast cell infiltrate is stained for KIT, tryptase, and CD25 (not shown).

Liver

It is likely that involvement of the liver is more frequent in SM than would be supposed from clinical findings alone.[132-134] Even in

patients without significant hepatomegaly and normal liver enzyme levels, microscopy may reveal small periportal or intrasinusoidal MC infiltrates. Because intrasinusoidal MCs are never encountered in normal or reactive states, such findings can be regarded as proof of involvement by mastocytosis (**Fig. 49-11**). In almost all cases, the portal triads are the main site of infiltration and show fibrotic enlargement. Accordingly, liver fibrosis is a frequent finding in mastocytosis and may even be associated with clinical signs of portal hypertension,[135] especially in ASM and MCL. Cirrhosis does not develop and therefore should not be regarded as a consequence of MC infiltration. However, in most patients with advanced SM with marked liver involvement (C finding), signs of liver fibrosis, ascites, and elevated liver enzyme levels (especially alkaline phosphatase) will be present. As in other tissues, immunohistochemical staining for tryptase, KIT/CD117, CD25, and CD30 must always be performed to evaluate the number of infiltrating MCs and supported by sequencing techniques regarding at least the *KIT* gene to establish a definitive diagnosis. Periportal MC infiltrates may be accompanied by large numbers of lymphocytes, so a so-called low-grade lymphoma with liver involvement may initially be suspected in a small number of cases.

Lymph Nodes

Lymph node infiltration is seen in about half of the patients with SM, making it less frequent than involvement of the BM, spleen, and liver.[130,136] Whereas enlargement of abdominal lymph nodes is found in some patients with advanced SM, involvement of peripheral lymph nodes is very rare. On histologic evaluation, the enlarged

lymph nodes almost always exhibit MC infiltration, which may be minimal and therefore difficult to detect. Generalized lymphadenopathy is a rare finding in SM and is usually associated with an aggressive clinical course and sometimes with eosinophilia. This particular rare presentation of ASM has previously been described as lymphadenopathic mastocytosis with eosinophilia.[137] Because lymph nodes in normal and reactive states often contain large numbers of MCs located predominantly in the sinuses, it can be difficult to confirm or to exclude involvement by mastocytosis. The most relevant findings concern the distributional pattern of MCs. Compact MC infiltrates within the paracortical regions or the pulp can be regarded as evidence of nodal involvement by mastocytosis (**Fig. 49-12**). These infiltrates are often small and are visible only when immunostaining with an antibody against tryptase is performed. Again, CD25 and CD30 stains may be helpful to raise suspicion for the presence of neoplastic MCs and, supported by results of sequencing techniques regarding at least the *KIT* gene, enable establishment of the SM diagnosis. Loosely scattered intrasinusoidal MCs may be numerous in reactive states (e.g., in a node draining an invasive cancer) but may be also observable in mastocytosis. In patients with known mastocytosis, a significant increase in intrasinusoidal MCs should be regarded as specific involvement, even if there are no compact infiltrates. As in other tissues involved by mastocytosis, reticulin or even collagen fibrosis is a consistent finding, but eosinophilia, plasmacytosis, and follicular hyperplasia are not present in all cases.

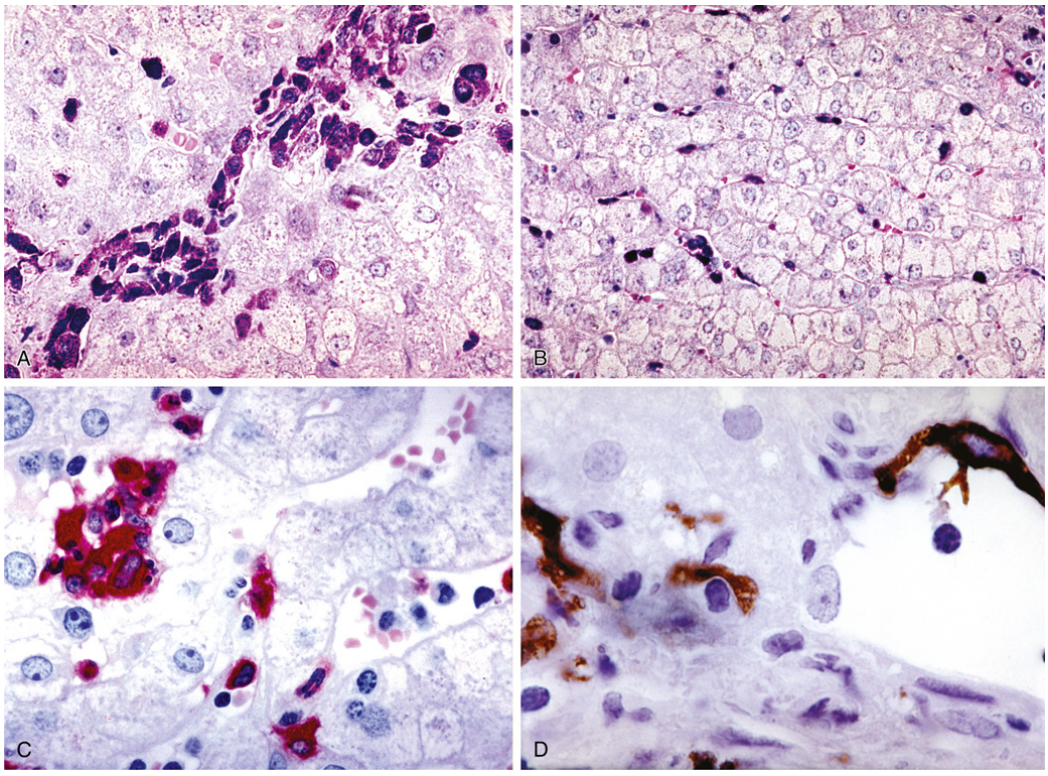

FIGURE 49-11 Liver findings in systemic mastocytosis.A, On Giemsa stain, the portal triads are infiltrated by strongly metachromatic mast cells in a case of indolent systemic mastocytosis. **B,** In the same case, there are loosely scattered intrasinusoidal mast cells in otherwise normal liver tissue. Although there are no compact infiltrates, such findings are interpreted as involvement by mastocytosis. **C,** At higher magnification, the same case shows pleomorphic mast cells strongly reactive with chloroacetate esterase but negative for myeloperoxidase (not depicted). **D,** Immunostaining for tryptase reveals some

unusual stellate mast cells resembling endothelial cells.

Gastrointestinal Tract

An increase in loosely distributed reactive MCs (MC hyperplasia) is a common finding in inflammatory processes involving the GI tract mucosa, and GI symptoms are frequent in patients with SM; GI symptoms in SM are mostly caused by MC mediators and not by MC lesions of the GI tract.[138] Thus, it may be difficult to determine whether the GI tract is directly involved by mastocytosis, even if immunohistochemistry is performed.[110,139-141] In these cases, immunohistochemical staining with antibodies against tryptase, KIT/CD117, CD25, and CD30 should be performed to determine the distribution of MCs and to detect small groups or compact infiltrates of MCs. As always, special care must be taken to ensure the proper recognition of CD25-positive MCs because some lymphocytes also express this antigen. Tryptase expression in MCs of SM in the GI tract is often variable and reduced compared with normal MCs.[110] Compact intramucosal MC infiltrates are relatively rare, but as in the BM and other tissues, these are the histologic hallmark of involvement by mastocytosis (**Fig. 49-13**). Such dense MC infiltrates are often located in the subepithelial layers of the *lamina propria*.[110] The small and large bowel are more often involved in SM than the stomach. Surprisingly, one study detected a decrease of intramucosal MCs in patients with SM compared with those of patients exhibiting pure CM and normal controls, and expression of CD25 by intramucosal MCs was not seen.[142] There are several different forms

of involvement of the GI tract by SM that will allow different levels of diagnostic certainty, especially if supported by sequencing results:

- Loosely scattered MCs expressing CD25 or carrying the *KIT* D816V mutation (usually seen in patients with known SM). However, diagnostic criteria of mastocytosis involving the mucosa are not fulfilled, and a preliminary diagnosis of monoclonal MC activation syndrome (MCAS) can be established.
- Disseminated nodular (granulomatous) compact MC infiltrates (comparable to findings in other organs, especially the BM). If MCs express CD25 and/or CD30 or carry the mutation *KIT* D816V, the diagnostic criteria of SM (involving the mucosa) are fulfilled.
- Bandlike, subepithelial, compact MC infiltrates (detectable only in GI tract mucosa). If MCs express CD25 and/or CD30 and/or carry the mutation *KIT* D816V, the diagnostic criteria of SM are fulfilled.
- Diffuse-compact MC infiltrates distorting preexisting cryptal structures and mimicking inflammatory bowel disease. Expression of CD25 and/or CD30 by MCs and/or demonstration of *KIT* D816V mutation allows the diagnosis of SM.
- Sarcomatous destructive growth. SM should be excluded by proper study of the recommended diagnostic SM criteria.

Skin

The histopathologic findings in patients with CM vary greatly, irrespective of the age at onset, but there is generally good

correlation with the macroscopic appearance of the lesions.[40,143,144] Disseminated perivascular and periadnexal MC infiltrates throughout the dermis is the most common cutaneous pattern and is associated with MPCM. MCs usually show an abundance of intracytoplasmic granules and are therefore strongly metachromatic. In longer-standing lesions, the basal layers of the epidermis show marked hyperpigmentation caused by an increase in melanin, producing the lesions' red-brown color. Only rarely is the number of melanophages in the dermis increased. An increase in reticulin and collagen fibers is almost always seen in CM. The number of eosinophils and lymphocytes is mostly slightly or moderately increased. Although mastocytoma and the rare nodular or plaquelike variants of MPCM exhibit strands and sheets of strongly metachromatic round MCs within a thickened fibrotic dermis, the increase in MCs in patients with what was previously known as the telangiectatic subtype of CM (*telangiectasia macularis eruptiva perstans* [TMEP]) may be minimal and detectable only by immunostaining for tryptase. TMEP is no longer recognized as a specific subtype of CM, as such lesions are included in the MPCM subtype. In this subtype, MCs accumulate in the upper third of the dermis and often assume a spindle shape. A bandlike infiltrate consisting almost exclusively of MCs is seen in the subepidermal connective tissue in the rare erythrodermic subtype of CM. In contrast to other involved tissues, expression of CD2, CD25, or CD30 is variable in cases of clinically and histologically diagnosed CM; therefore, respective negativity is not as useful as in other (extracutaneous) tissues.

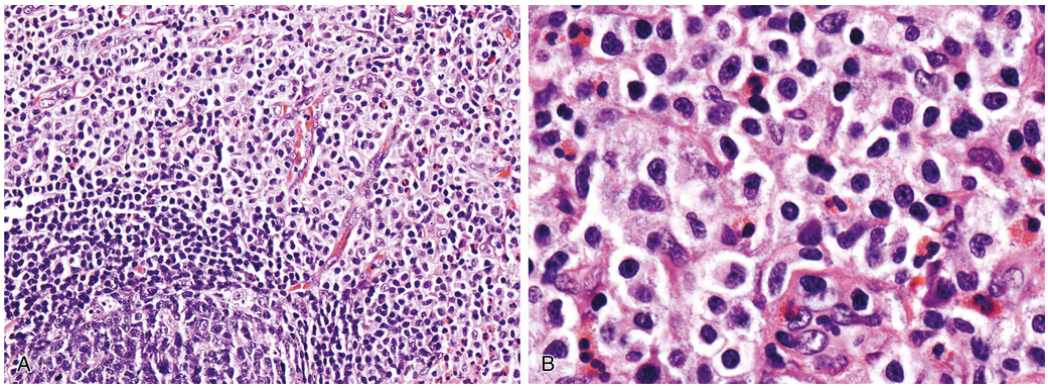

FIGURE 49-12 Lymph node findings in systemic mastocytosis.A, Diffuse infiltration and partial effacement of the paracortical lymph node architecture by metachromatic mast cells. Such histologic findings are typical of enlarged peripheral lymph nodes in patients with long-standing cutaneous mastocytosis (urticaria pigmentosa) and signify a diagnosis of indolent systemic mastocytosis. **B,** At higher magnification (same case), the mast cells have abundant granular or clear cytoplasm with admixed eosinophils.

FIGURE 49-13 Systemic mastocytosis involving the duodenum. The lamina propria of the duodenal mucosa is densely infiltrated by slightly pleomorphic mast cells exhibiting strong reactivity for chloroacetate esterase. The patient had complained of diarrhea. Because there was also mild focal involvement of the bone marrow, this case could be classified as indolent systemic mastocytosis. Note that the epithelium is completely intact and contains no mast cells.

Differential Diagnosis

Tables **49-4** and **49-5** summarize the major conditions that must be considered in the differential diagnosis of mastocytosis. One main problem is the recognition of MC hyperplasia, which can be pronounced in solid tumors of neurogenic origin and in a few hematologic malignant neoplasms, especially in cases with lymphoplasmacytic lymphoma, and in patients receiving stem cell factor (KIT ligand).[145] However, even if the reactive increase in MCs is massive, compact infiltrates are virtually absent; they have been detected only in a few cases of stem cell factor–induced MC hyperplasia.[146] It is therefore crucial to look carefully for compact or dense MC infiltrates, which should consist of ≥15 cells. The compact infiltrates in many cases of ISM are typically intermingled with many small lymphocytes, which sometimes form follicle-like structures, making it difficult to distinguish this disorder from so-called low-grade lymphoma involving the BM.[119,120] Myeloid neoplasms, especially myelodysplastic and myelodysplastic/myeloproliferative neoplasms, occasionally show a marked increase in atypical, sometimes blast-like MCs in the BM and peripheral blood. Such phenomena are best considered signs of MC differentiation and must be distinguished from "true" mastocytosis in the context of the results of CD25 and CD30 staining and ddPCR for the *KIT* D816V mutation. If the number of atypical metachromatic cells in the BM smear or peripheral blood is >10% and SM criteria are not met, the designation of MML is appropriate (**Fig. 49-14**).[105,118,147] MML lacks MC aggregates, expression of CD25 (rare positive instances being described), and the *KIT* D816V mutation (though other *KIT* mutations can be found in a subset of cases).[118] The existence of

tryptase-expressing blast cells in cases of AML can be designated tryptase-positive AML, which often belongs to AML with minimal differentiation or without maturation (**Fig. 49-15**). Blasts in both MML and tryptase-positive AML will often co-express CD34, though MCs in mastocytosis (and reactive MCs) are negative for CD34. This immunohistochemical finding is reflected in an elevation of the serum tryptase level, which is sometimes extremely high and can exceed levels found in patients with SM.[148] However, such cases should not be classified as mastocytosis unless SM criteria are met (SM-AML). When tryptase immunohistochemistry is routinely used in the workup of BM trephine biopsy specimens, the described phenomenon termed tryptase-positive compact round cell infiltrate of the BM (TROCI-bm) is an important diagnostic checkpoint. By definition, TROCI-bm may be focal or diffuse and consists exclusively of round (not spindle-shaped) cells forming compact (dense) tissue infiltrates.[149] The differential diagnosis of TROCI-bm includes six distinct but rare hematologic neoplasms (tryptase-positive AML, MCL, SM, MML, and acute and chronic basophilic leukemia) that can be separated only with a panel of antibodies mainly directed against MC-related and basophil-related antigens such as KIT/CD117, CD25, CD30, 2D7, and BB1 and—in equivocal cases—*KIT* sequencing results applying a sensitive technology. Because the BB1 and 2D7 antigens are expressed preferentially on basophilic granulocytes, respectively positive focal TROCI-bm in the setting of CML indicates secondary basophilic leukemia and therefore disease progression.[64,65] TROCI-bm with co-expression of KIT/CD117, CD25, and/or CD30 indicates SM, whereas lack of CD25 but positivity for CD30 in this setting is typical of WDSM.[59,71]

Finally, co-expression of CD34 by tryptase-positive cells in diffuse TROCI-bm indicates either MML or tryptase-positive AML.

Table 49-4

Differential Diagnosis of Mastocytosis

Diagnosis	Definition
Mast cell hyperplasia	Nonneoplastic, local, or systemic increase in mast cells
Myeloid neoplasm with mast cell differentiation but lacking SM criteria	MDS, MPN, or AML with focal increase in neoplastic atypical mast cells, especially myelomastocytic leukemia
Tryptase-positive AML or AML with *KIT* D816V mutation	AML with aberrant expression of tryptase but without compact infiltrates or other criteria for SM
Mastocytosis (mast cell neoplasm)	Typical skin lesions of cutaneous mastocytosis and/or fulfilled SM criteria, or localized mast cell tumor

AML, Acute myeloid leukemia; *MDS,* myelodysplastic syndrome/neoplasm; *MPN,* myeloproliferative neoplasm; *SM,* systemic mastocytosis.

Table 49-5

Differential Diagnosis of Subtypes of Mastocytosis

Subtype	Differential Diagnosis
CM	ISM
ISM	MCH, MCAS, BMM, SSM
SM-AMN	Tryptase-positive AML, MML, SSM, ASM
ASM	SSM, aleukemic MCL, lymphoma*
MCL	MML, ASM, chronic basophilic leukemia
MCS	High-grade sarcoma, myeloid/histiocytic sarcoma, melanoma, mastocytoma

AML, Acute myeloid leukemia; *ASM,* aggressive systemic mastocytosis; *BMM,* bone marrow mastocytosis; *CM,* cutaneous mastocytosis; *ISM,* indolent systemic mastocytosis; *MCAS,* mast cell activation syndrome; *MCH,* mast cell hyperplasia; *MCL,* mast cell leukemia; *MCS,* mast cell sarcoma; *MML,* myelomastocytic leukemia; *SM-AMN,* systemic mastocytosis with associated myeloid neoplasm; *SSM,* smoldering systemic mastocytosis.

* Lymphadenopathic mastocytosis with eosinophilia, a previously described subvariant of SSM, may present with massive (abdominal) lymphadenopathy and thereby mimic a lymphoma.

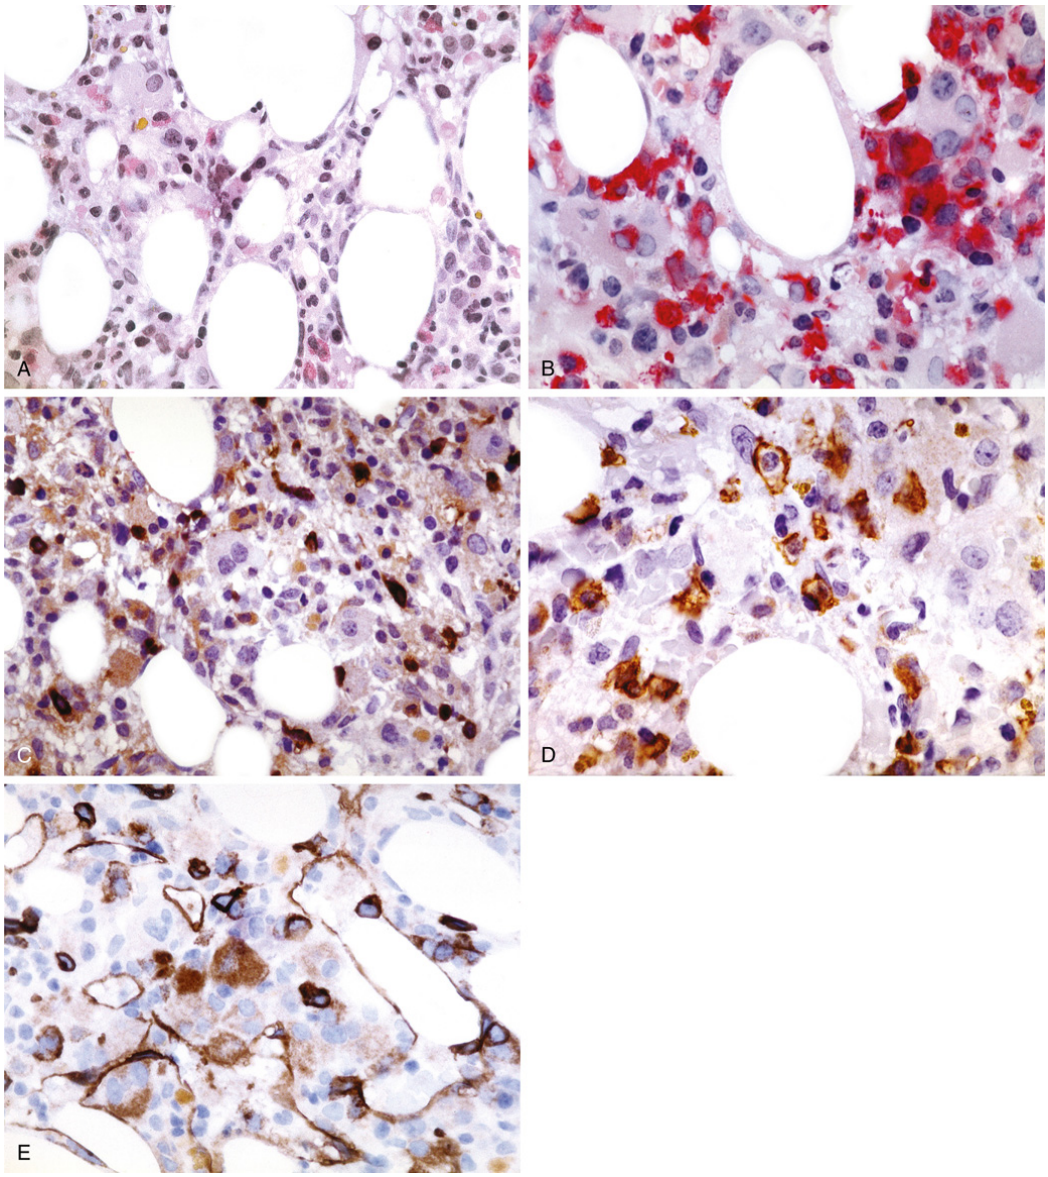

FIGURE 49-14 Myelomastocytic leukemia. Normocellular bone marrow specimen with dysplastic features. **A,** H&E (hematoxylin and eosin) staining reveals a relatively homogeneous picture, with some scattered micromegakaryocytes. **B,** In contrast, the chloroacetate esterase stain clearly indicates atypical neutrophilic granulopoiesis with a left

shift. **C,** Immunostaining for tryptase reveals a significant increase in round and spindle-shaped mast cells, which are strongly stained but do not form dense infiltrates. **D,** These cells are confirmed to be mast cells and not atypical basophils by immunostaining with an antibody against CD117. **E,** The number of CD34-positive progenitor or blast cells is also significantly increased, but compact infiltrates cannot be detected. Altogether, the CD34-positive cells constitute 5% to 10% of all nucleated cells, which signifies a diagnosis of myelodysplastic syndrome with excess blasts. Because a small number of circulating mast cells was also detected, this case shows the typical features of myelomastocytic leukemia and cannot be diagnosed as mastocytosis or mast cell leukemia (compare with **Fig. 49-3**).

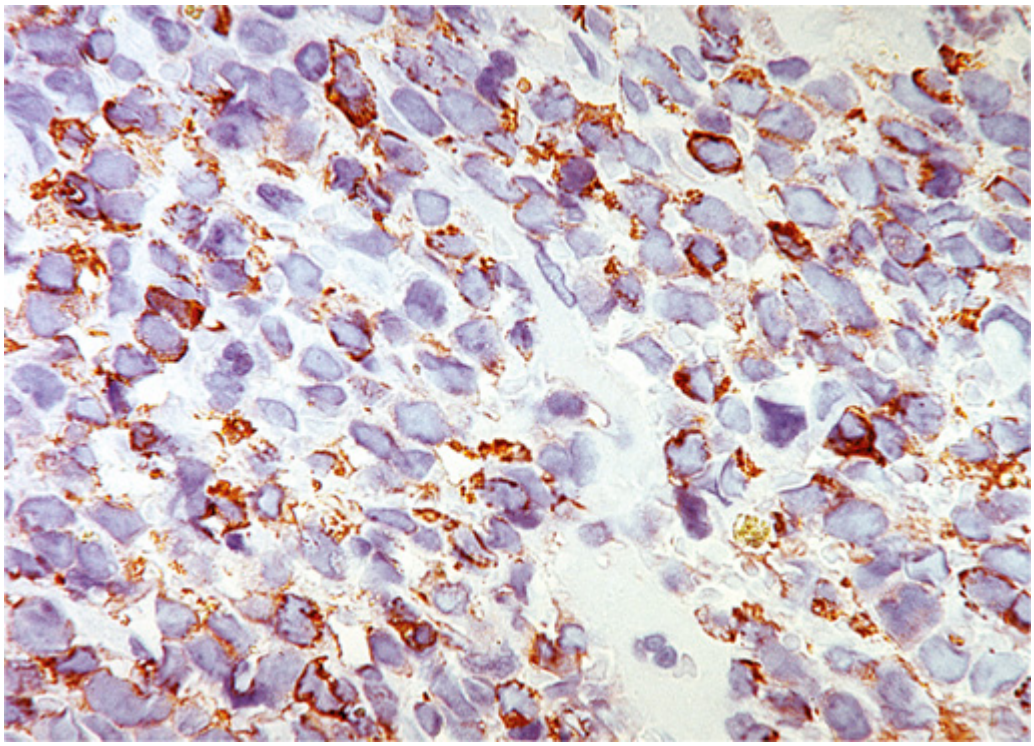

FIGURE 49-15 Tryptase-positive myeloid blast crisis of chronic myeloid leukemia. Immunostaining for tryptase reveals strong focal cytoplasmic reactivity in most of the blast cells. The blast cells also expressed KIT (CD117).

If the diagnostically relevant antibodies against tryptase and KIT/CD117 are not applied, the differential diagnosis includes a much broader range of reactive and neoplastic disorders. In general and considering extramedullary sites, granulomatous diseases, osteodystrophy (also called tunneling fibro-osteoclasia) in chronic renal insufficiency/hyperparathyroidism, histiocytoses, myelofibrosis, angioimmunoblastic and anaplastic large cell T-cell lymphoma, multiple myeloma, Hodgkin lymphoma, seminoma, GI stromal tumor (GIST), sarcomas with spindle cell and epithelioid

morphology, and melanoma represent the most important considerations.[55] In cases of SM-AMN, the associated hematologic neoplasm often dominates the histologic picture and may obscure small MCs, which may even become visible upon therapy for the former.[123,124]

The principal key to the diagnosis of mastocytosis in the BM is to be aware that clusters of fibroblast-like spindle cells or epithelioid cells are almost always the primary histologic sign of SM. Spindle cells are extremely rare in other hematopoietic neoplasms but may be seen in reticulum cell sarcoma and multiple myeloma. Infiltrates or metastases of spindle cell sarcomas are also exceedingly rare. GIST with expression of KIT might be the only difficult differential diagnosis; however, GIST involving the BM has not been reported.

Mast Cell Activation Syndrome

Mast cell activation syndrome (MCAS) applies to conditions in which patients experience symptoms caused by the release of an inappropriate amount of MC mediators fulfilling all three of the following criteria: (1) typical clinical signs of severe, recurrent, acute, systemic MC activation (e.g., pruritus, flushing, blistering, urticaria, headache, diarrhea, abdominal pain, vomiting, fainting, respiratory problems, anaphylaxis); (2) involvement of MC demonstrated by biochemical analyses (preferably through an increase in tryptase following the 20% + 2 ng/mL formula, which means event-related transient elevation of the serum tryptase level by at least 20% over the individual baseline plus 2 ng/mL absolute within a 2- to 4-hour window after the anaphylactic reaction); and (3) symptoms respond to treatment with MC-stabilizing agents or drugs targeted against

MC mediator production, secretion, or receptor binding.[150-152] Given the definition, it is obvious that MCAS is neither a morphologic diagnosis nor an ICC/WHO subentity of mastocytosis. Nevertheless, and as comprehensible from the list here, at least one variant represents a clonal MC condition.

Five different variants of MCAS are currently recognized[150-152]:

1. Monoclonal (primary or clonal) MCAS; defined by the presence of *KIT* mutation(s) or the aberrant expression of CD25 on MCs as a surrogate of clonality (irrespective of whether other diagnostic criteria of mastocytosis are met),
2. Secondary MCAS; associated with an underlying nonneoplastic disease (e.g., IgE-dependent allergy or other hypersensitivity reaction),
3. HαT-positive MCAS; in which HαT is detected, all diagnostic MCAS criteria are fulfilled, and no related allergic cause or underlying clonal MC disease is detected,
4. Combined MCAS; in which patients with MCAS have two or more of the following: (a) CM or SM, (b), overt allergy/atopic disease, and (c) a known genetic predisposition such as HαT (in these patients, the risk for severe anaphylaxis is extremely high),
5. Idiopathic MCAS, in which no related reactive disease, IgE-dependent allergy, HαT, or neoplastic/clonal MCs are found.

MCAS is not a histopathological diagnosis, yet there is a clear role for the pathologist in the classification ruling out monoclonal MCAS by high sensitivity and specificity assays to detect *KIT* mutations (e.g., ddPCR) and/or expression of CD25.

Classification

We describe herein each of the variants of mastocytosis defined in the ICC 2022 and the proposed WHO 5th edition classification (Boxes **49-1**–**49-3**).[12,105,153] Transitions between disease categories may occur, and the exact diagnosis may depend on the accuracy of the investigatory procedures.[90,154] The incidence of transition to a higher disease category is unknown. In advanced SM involving multiple myeloid lineages, the borders between ASM, SM-AMN, and MCL may occasionally be blurred.[155] In addition, the BM smear may sometimes be of poor quality or difficult to examine because of contamination with blood cells or because only a few BM cells are aspirated (dry tap). In regard to ASM/MCL, this has been accounted for by the ICC 2022 recognizing that diffuse, dense infiltration of atypical immature MCs may support the diagnosis of MCL.[12] In adult patients with CM who have not undergone a BM examination, it is recommended to establish the presumptive diagnosis of mastocytosis in the skin (MIS)[156] and prompt an extensive workup—including peripheral blood analysis for mutant *KIT* by means of a sensitive technique—and perform a BM biopsy later to exclude SM, as it is expected in >90% of adult cases of MIS.[40] Because most pediatric cases are pure CM,[157] BM biopsy is usually not recommended unless there are clinical or laboratory signs of systemic advanced or aggressive disease variants, such as marked cytopenia, a very high and steadily increasing serum tryptase level, organomegaly and/or mutant *KIT* with high VAF in the peripheral blood.[158,159] **Table 49-5** summarizes the defined disease categories and the main diseases and conditions to consider in the differential diagnosis.

Cutaneous Mastocytosis

Definition

CM is an accumulation of MCs within the dermis associated with typical clinical findings, usually disseminated maculopapular lesions of CM. CM can be diagnosed only if there are no signs of systemic disease, i.e., no criteria to diagnose SM. Multifocal compact MC infiltrates (major SM criterion) are not found on histologic evaluation of the BM or in other extracutaneous tissues. However, in patients with CM, one or two minor SM criteria may be detected, and in a proper context, they may fulfill diagnostic criteria for monoclonal MCAS. The skin lesions in the majority of patients with ISM are clinically and histologically indistinguishable from pure CM.

Epidemiology

CM is the most common variant of MC disease, especially in children (juvenile CM), and it reportedly accounts for more than 80% of cases. In children, there is a male predominance (approximately 1.3×), and 90% of the affected present as MPCM (75% of cases) before the age of 2 years, mostly in the first 6 months of life.[157,159] However, if adult patients with mastocytosis are staged—especially with an appropriate investigation of BM trephine specimens, including immunohistochemistry (e.g., tryptase and CD25), and molecular analyses for *KIT* codon 816 mutations—the incidence of SM markedly increases.[40]

Clinical Features

Three major clinical types of CM are recognized[156,160]:

1. MPCM, formerly termed UP, is the most common subtype. It can be further subdivided into two clinical variants: a monomorphic variant that can be seen in children and adults and that is characterized by small, round, brown or red maculopapular lesions and a polymorphic variant that is almost always restricted to children and is characterized by larger lesions of variable size and shape, often accompanied by plaques or nodules.
2. Diffuse CM is very rare and is almost always seen in young children.
3. Mastocytoma of the skin is also rare, usually solitary, rarely multilocalized (i.e., <4 lesions, otherwise MPCM should be diagnosed), occurs almost exclusively in children, and has a tendency to regress spontaneously.

TMEP should not be regarded as a special type of CM and should be included in the MPCM subtype, as it is usually accompanied by lesions typical of MPCM.

MPCM can be detected in childhood (>90% of cases) and less frequently in adulthood (<10% of cases). An important aspect is that children with MPCM can further be divided into those with monomorphic small-sized skin infiltrates and those with polymorphic (smaller and larger) skin lesions, a distinction that is of prognostic significance.[156]

Another important aspect is that adults with CM (MPCM) have a significantly better prognosis concerning progression-free survival than adults with ISM.[160] Therefore, a BM investigation is recommended in all adult patients with MPCM-like skin lesions (suspected SM). If such patients refuse a BM biopsy, the diagnosis

CM or SM cannot be established, and the provisional diagnosis should be MIS.[14,39,160]

Morphology

The histologic picture in typical cases of MPCM is one of disseminated aggregates of mature-appearing, strongly metachromatic, mostly round to ovoid MCs found mainly around small blood vessels and adnexal structures within the dermis (**Fig. 49-16**). Prominent signs of epidermotropism are not seen. Confluent clusters of MCs are rarely found. Some cases may display very subtle changes that will be only appreciated with immunohistochemistry. Diffuse CM can be recognized by a diffuse, bandlike, subepidermal infiltrate of MCs often accompanied by edema, whereas mastocytoma shows nodular compact infiltrates, often elevating the overlying intact epidermis.

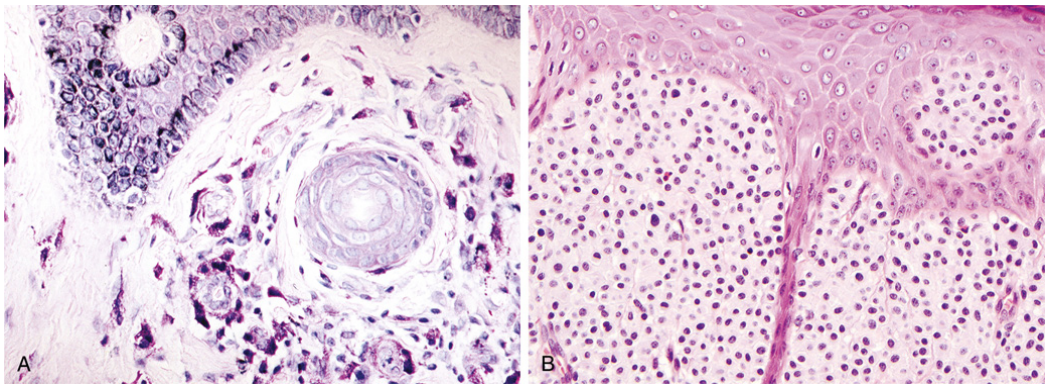

FIGURE 49-16 Cutaneous mastocytosis.A, Giemsa stain of a skin biopsy specimen from a patient with long-standing maculopapular cutaneous mastocytosis. Note the preferential perivascular and periadnexal localization of the metachromatic mast cells, without the formation of larger infiltrates. Hyperpigmentation of the basal layer of the epidermis is responsible for the typical red-brown macroscopic appearance of the lesions. **B,** H&E (hematoxylin and eosin) staining of a skin biopsy section from a child with mastocytoma. Note the sheets of slightly pleomorphic mast cells within the dermis.

Immunophenotype and Genetics

Virtually all MCs in all cases of CM express tryptase and KIT/CD117, whereas co-expression of CD25 and CD30 varies considerably. The MCs in CM, unlike those in SM, usually also express chymase, although this is of little diagnostic relevance. The frequency of expression of CD2 in CM is not known.

The *KIT* D816V mutation in exon 17 is only present in a third of pediatric patients with CM.[161-163] Mutations outside the exon 17, especially in the extracellular domains (exon 8 and 9), are detected in another third of patients, and in another third of patients, *KIT* is wild type. It is important to recall that the presence of a *KIT* mutation only in extracutaneous organs is a criterion for SM. When positive in CM, these mutations are usually detectable within the lesions and not in the peripheral blood; if detected in blood samples, they strongly indicate systemic disease.[164]

Postulated Cell of Origin

The postulated cell of origin is a committed MC precursor.

Clinical Course

The clinical course of CM is usually that of a benign dermatologic disorder, and spontaneous regression after a period of 12 to 13 years occurs in a significant proportion of juvenile cases.[156,157,162,165] So far, it remains unknown what factors predict persistence of CM lesions into adulthood. In patients with CM who present with small monomorphic skin lesions, the disease tends to persist into adulthood, and in some cases, SM is diagnosed later in life.[156] By contrast, in patients with polymorphic (larger and smaller irregular) lesions, the disease often resolves during or before puberty.[156] In line with this observation, this form of lesion is found only in children, whereas almost all adult patients present with small monomorphic lesions. Mastocytoma is often resected under suspicion of a nevus. In patients with diffuse CM, severe mediator-induced symptoms resulting from degranulation of MCs may occur, sometimes in form of life-threatening anaphylaxis. Serum tryptase is

normal in children with a mastocytoma and most children with MPCM but generally elevated in DCM, reflecting the high MC burden caused by the extensive skin involvement. Serum tryptase levels, peripheral blood *KIT* mutation status, peripheral blood counts, and other clinical signs should be evaluated in a child with CM to assess risk of systemic involvement.[166] In adults, the vast majority of patients with suspected CM will have ISM. However, as mentioned, CM can sometimes also be detected in adults. If the skin is the only diagnostic specimen and no BM investigation was performed, it is advised to diagnose MIS, not CM, and recommend additional diagnostic procedures (BM biopsy, high sensitivity *KIT* mutational testing of the peripheral blood).[40,55,153,156] It should be noted that adult-onset MIS and CM do not tend to spontaneously regress, and the affected individuals are at a much higher risk of experiencing anaphylaxis than children.[156]

Differential Diagnosis

Because of the typical dermatologic findings, including a positive Darier's sign, the diagnosis of typical MPCM is rarely missed. However, there are several atypical variants of MPCM that can be missed or confused, such as the nodular form, telangiectatic form, or plaque form of MPCM. Histopathologic features are nearly pathognomonic in MPCM. In adult patients with typical skin lesions (MPCM-like), a *KIT* mutation like D816V in peripheral blood leukocytes, and markedly (and persistently) elevated serum tryptase level (>30 ng/mL) without HαT, the diagnosis of ISM is more likely than that of CM. Thus, these findings in an adult require appropriate staging procedures, including histologic investigation of a BM biopsy

specimen. Mastocytoma may be misinterpreted as a malignant neoplasm unless appropriate stains (e.g., Giemsa, toluidine blue, tryptase) are performed. Of note, melanocytic tumors may express KIT/CD117, once again pointing toward the importance of always applying both tryptase and KIT/CD117 staining whenever mastocytosis is suspected.

Indolent Systemic Mastocytosis

Definition

ISM is defined by the presence of a diagnostic minimum of SM criteria (at least the major SM criterion[12] and the major and one minor SM criterion[13] or at least three minor SM criteria[12,13]) and absence of criteria to diagnose a more advanced type of SM. In fact, patients with ISM lack any C findings and have only one or no B findings. In addition, the diagnoses of SM-AMN/AHN and MCL have to be excluded (Boxes **49-1**–**49-3**).[12-14,39,153] From a histopathological point of view, multifocal MC infiltrates are detectable in at least one extracutaneous organ, usually the BM. Most patients have the typical skin lesions of MPCM. However, today, more and more patients with ISM without skin lesions are diagnosed and referred to as having BM mastocytosis (BMM). A clinically relevant involvement of lymph nodes, liver, spleen, or the GI tract mucosa is less frequent than in advanced SM. By definition, signs of organ failure are not present.

Epidemiology

ISM is the most common subtype of SM and is much more frequent than all the other defined SM subtypes put together.

Clinical Features

Because cutaneous involvement is present in most cases of ISM, the clinical picture is usually dominated by the typical skin lesions, signs of MC activation (usually in the form of mild mediator-induced symptoms but sometimes also in the form of severe symptoms), and osteopenia or osteoporosis. In those with an accompanying IgE-dependent allergy and/or HαT, the risk of anaphylaxis (MCAS) is high. In a subset of patients, osteoporosis with bone pain is a major complaint requiring specific therapy. The serum tryptase level exceeds 20 ng/mL in most patients with ISM. Organomegaly (hepatosplenomegaly or lymphadenopathy) is usually not found and would represent one (of at least two needed) B finding for the diagnosis of SSM.

Morphology

ISM is characterized by a multifocal, often paratrabecular, compact MC infiltrate in the BM (Figs. **49-17** and **49-18**). The MCs may sometimes be round, but in most patients with ISM, they are spindle shaped (atypical MC type I). In most cases, the degree of infiltration is low and does not exceed 10% of the section area. In most patients with ISM, the distribution of fat cells is normal, and hematopoiesis is intact in nonaffected BM sites. Mild reactive BM changes, including hemosiderosis, eosinophilia, lymphocytosis, and plasmacytosis, are frequently seen. An increase in reticulin or collagen fibers is confined to the compact MC infiltrates. Thickening of the bone trabeculae is typically found in ISM but is also seen in other SM variants.

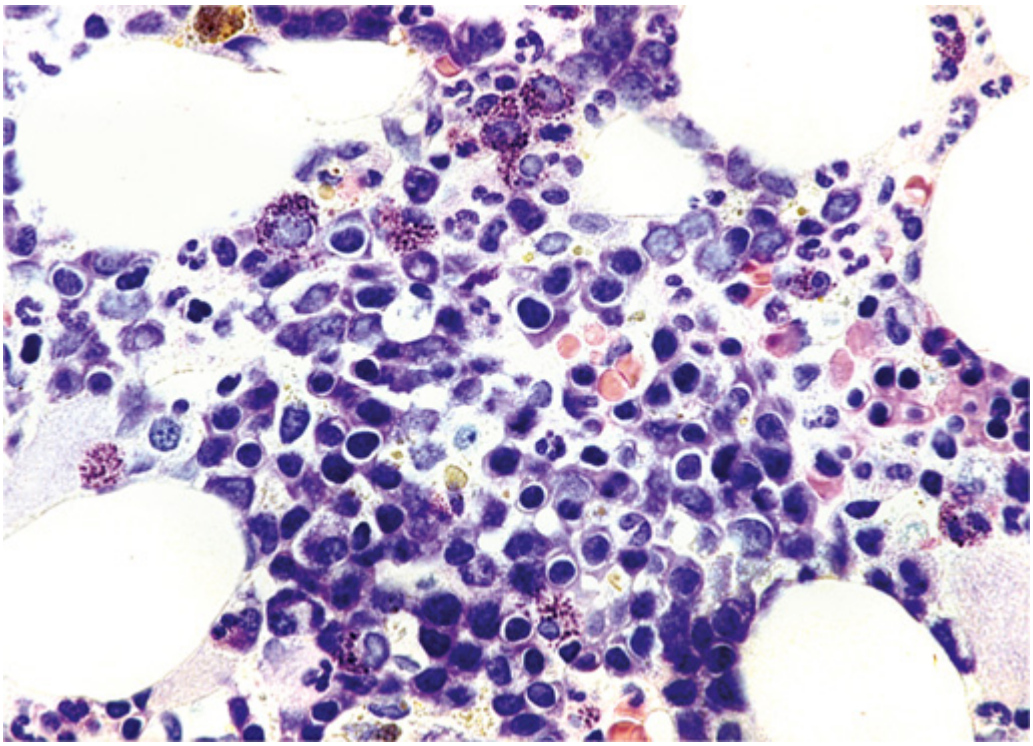

FIGURE 49-17 Mast cell hyperplasia. Slightly hypercellular bone marrow specimen with prominent erythropoiesis and an increase in loosely scattered metachromatic mast cells. This finding alone does not establish a diagnosis of indolent systemic mastocytosis, even in patients with known cutaneous mastocytosis and elevated serum tryptase levels. Note that the mast cells do not form compact infiltrates. This case illustrates the interstitial type of diffuse infiltration, which is typically seen in hyperplastic states (mast cell hyperplasia).

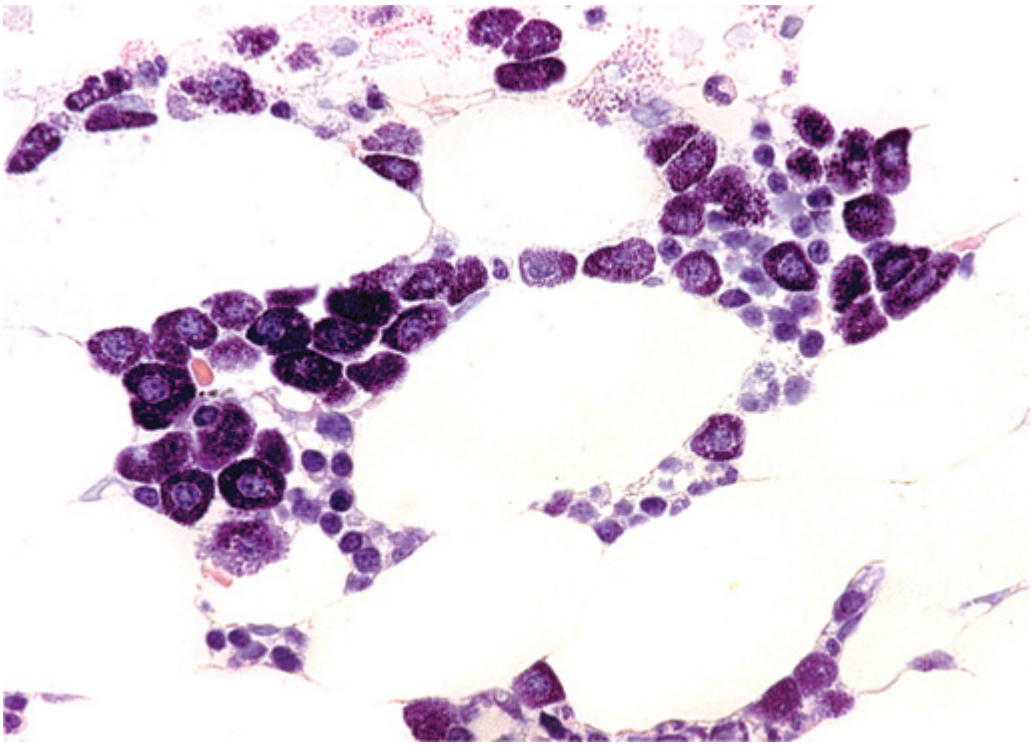

FIGURE 49-18 Indolent systemic mastocytosis. Hypocellular bone marrow specimen with a focal increase in strongly metachromatic mast cells. Because the patient was known to have mastocytosis in the skin, a diagnosis of indolent systemic mastocytosis was established (compare with **Fig. 49-17**). The finding of mast cell infiltrates in a hypocellular marrow specimen is uncommon.

Immunophenotype and Genetics

Immunostaining for tryptase and KIT/CD117 is crucial for the diagnosis of ISM to identify even very small compact MC infiltrates. The neoplastic MCs almost always co-express CD25 and often dim (but sometimes strong) CD30; in a subset of cases, CD2 is also

present but may be difficult to discern given the accompanying T-cell infiltration. In the rare cases of WDSM, however, expression of CD25 and CD2 is absent, whereas CD30 is brightly expressed in MCs. Focal accumulations of lymphocytes, composed of almost equal proportions of CD20-positive B cells and CD3-positive T cells, are found relatively often in the immediate vicinity of the compact MC infiltrates in ISM, but they are rarely seen in other variants of SM. MCs co-expressing tryptase and chymase (MC_{TC}) are seen relatively frequently in ISM and CM but are relatively rare in ASM and MCL. The latter entities exhibit a majority of MCs that express only tryptase (MC_T type).

The *KIT* D816 mutation is present in >90% of ISM, but >50 other rare *KIT* mutations have been described.[18] *KIT* D816V VAF in serum and BM is usually low (<10%) in ISM, also pointing toward the unilineage involvement.[167] Indeed, the *KIT* D816V mutation in non-MC lineages (multilineage involvement) is only rarely found in ISM compared with advanced SM.[74] The consensus group and the proposed WHO 5th edition account for that and promote *KIT* D816 mutation VAF ≥10% in BM or peripheral blood as a B finding.[13,39] Use of a highly sensitive PCR assay for detection of *KIT* D816V mutation is recommended.[12,153] Other *KIT* mutations and wild-type *KIT* are more frequently encountered in SM with well-differentiated morphology[59] or in advanced SM. If *KIT* D816V is negative, exclusion of *KIT* mutational variants is needed in suspected SM, as any activating *KIT* mutation qualifies as a minor diagnostic criterion.[12,13] If no *KIT* mutation is detected, the presence of M/LN-Eo and tyrosine kinase gene fusion must be excluded.[90] Usually, no other mutations are detected in BM affected by ISM. Yet in elderly

patients, characteristic CHIP-mutations with low VAF may be encountered, which may be challenging to interpret.

Postulated Cell of Origin

The postulated cell of origin is a mast cell committed stem/progenitor cell.

Clinical Course

The course of the disease is usually benign. Mediator-related symptoms and/or complications caused by the accompanying osteopathy are often leading. Patients have a slightly increased risk for development of an associated myeloid neoplasm or advanced SM compared with those of adult patients with CM and the general population.

Bone Marrow Mastocytosis and Other (Sub)Variants and Differential Diagnoses

BMM is recognized as a clinicopathologic variant of ISM in the ICC 2022 and as a separate SM entity by the consensus group and in the proposed WHO 5th edition.[12-14,39] BMM is defined by isolated (preferential) BM involvement with mastocytosis in the absence of skin lesions, lack of (any) B findings, and a tryptase level <125 ng/mL.[39] Regarding progression, the prognosis of patients with BMM is favorable compared with other patients with ISM.[168] In addition, patients with BMM have a high risk of developing severe anaphylaxis (>60% of patients) after *Hymenoptera* insect venom exposure (stings), which is much more frequent than in patients with typical ISM (approximately 15%).[168] BMM accounts for the majority of cases formerly designated eosinophilic fibrohistiocytic BM

lesions.[9] Compared with typical ISM, BMM shows lower serum tryptase levels, a male predominance, significantly older age at presentation, lower MC burden, and fewer MC-related symptoms between acute episodes.[168,169] Because of the lower MC burden, the major criterion is often not met, so the diagnosis mostly relies on the presence of the three minor SM criteria; therefore, the use of a very sensitive technique to detect a *KIT* mutation is of importance. Because serum tryptase may not be routinely measured in patients presenting with anaphylaxis, BMM is likely underrecognized. Although patients with BMM have an excellent prognosis in terms of progression, they are at risk for potentially life-threatening allergic reactions and bone fractures. Another important aspect is that most patients with ASM and MCL also lack skin lesions. Therefore, it is of great importance to delineate between advanced SM (ASM/MCL) and BMM. Whereas in BMM no B or C findings and no circulating MCs are seen and serum tryptase levels and *KIT* mutational VAFs are low, a markedly elevated serum tryptase, C findings, circulating MCs (in MCL) and high *KIT* mutational VAFs (often accompanied by other mutations) are detected in ASM and/or MCL.

WDSM is characterized by the presence of enlarged, round, well-granulated MCs forming multifocal infiltrates; CD2 and CD25 are usually not expressed, and the *KIT* D816V mutation is lacking; this constellation is commonly seen in a characteristic clinicopathologic setting.[59] Yet, WDSM morphology is detectable in patients with ISM (often BMM) and SSM and even sometimes in those with MCL. Therefore, it is currently considered a morphologic pattern and not as a separate SM subentity.[12,13]

Smoldering Systemic Mastocytosis

SSM was initially considered a subvariant of ISM, assuming an intermediate position between ISM and ASM, exhibiting at least two B findings but no C findings and no AMN. The patients often display organomegaly without functional impairment (i.e., hepatomegaly and/or splenomegaly and/or >1 cm lymphadenopathy on palpation or imaging without ascites, portal hypertension, or hypersplenism; B finding #3). The degree of BM infiltration is higher than that seen in typical ISM, exceeding 30% of the section area (B finding #1). Cytopenia or cytosis not meeting criteria for C findings and not explained by another reactive process or AMN can be observed and is considered a B finding in the ICC 2022.[12] Signs of mild hematopoietic dysplasia or mild myeloproliferative features may be present in the BM (not meeting the diagnostic criteria for AMN/AHN), which is still considered a B finding by the consensus group and in the proposed WHO 5th edition (but not in the ICC 2022).[13,14,39] A markedly elevated serum tryptase level (>200 ng/mL) is seen in most patients with SSM (B finding #1).[170,171] In 2022, both classifications recognize SSM as a separate variant of SM.

Systemic Mastocytosis With an Associated Myeloid/Hematologic Neoplasm

Definition

The diagnosis of SM-AMN (AHN according to the proposed WHO 5th edition) can be made only when there is clear evidence of both SM and concurrent myeloid neoplasm.[153] SM-AMN/AHN meets the diagnostic criteria of both SM and the associated myeloid neoplasm (ICC 2022) or any hematologic neoplasm (proposed WHO 5th edition), both of which should be classified according to established

criteria. As hematologic neoplasms accompanying SM are almost exclusively of myeloid origin—and often of clonality proven to be shared with the SM[46,68]—and co-occurring lymphoid or plasma cell neoplasms are rare and considered to be clonally unrelated,[46,47,126] the latter two groups are excluded as associated neoplasms in the ICC 2022.[12] The diagnosis of SM-AMN/AHN can be difficult to establish because the histologic and cytologic features of SM may be obscured by the associated malignant neoplasm. In some patients, diagnosis and subtyping of the AMN/AHN are possible only in the blood owing to an extensive compact infiltration of the BM, mimicking pure ASM or MCL at first glance. In some patients, the initial BM biopsy specimen enables establishment of a diagnosis of SM-AMN/AHN, whereas in a following biopsy, progression of SM with extensive infiltration of the BM may obscure the AMN. The following diseases have been identified within the setting of SM-AMN: MDS, AML (most commonly AML t[8;21][q22;q22.1]/*RUNX1*::*RUNX1T1*), CML, MPN, and MDS/MPN (most commonly CMML); because of the common co-occurrence of SM in CMML and AML t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1,* active search by means of tryptase staining on a regular basis is advisable in such instances.

Epidemiology

SM-AMN/AHN is the second most common subtype of SM. However, its true incidence is probably underestimated because the SM component is often missed owing to the dominance of the AMN. Cases have been recognized in which the presence of SM was

disclosed after therapy for AML, enabling the retrospective diagnosis of SM-AML.[55,124,126,172]

Clinical Features

Clinical features are generally dominated by the non-MC AMN, including significant cytopenia(s) or cytosis, monocytosis and/or eosinophilia, splenomegaly, and elevated LDH.[153] In addition, high *KIT* D816V VAF (usually much higher than anticipated from the MC numbers in the biopsy), and additional somatic mutations in genes associated with myeloid malignancies (particularly if occurring in combination) should raise a high degree of suspicion for an AMN in SM. The typical skin lesions seen in ISM are present in <50% of patients with SM-AMN/AHN.[173-175]

Morphology

The histologic picture of SM-AMN/AHN in the BM is heterogeneous and largely dependent on the type of AMN/AHN (**Fig. 49-19**). The BM almost always exhibits marked hypercellularity, with subtotal depletion of fat cells. Both multifocal compact MC infiltrates and the typical morphologic findings of AMN/AHN must be detectable.[12,13] A few cases of pure CM with AMN/AHN have also been reported.[176] We think such cases should not be termed SM (or SM-AMN/AHN) and that they represent coincidental findings.

If eosinophilia is present, the presence of tyrosine kinase gene fusions associated with M/LN-Eo must be excluded.[90] Although usually mutually exclusive, rare cases with both *KIT* mutation and tyrosine kinase gene fusion have been reported.[177] In such an exceptional instance, the M/LN-Eo would represent the AMN, but such cases should only be diagnosed in the presence of unequivocal

molecular evidence of both a *KIT* mutation and a characteristic M/LN-Eo gene fusion.

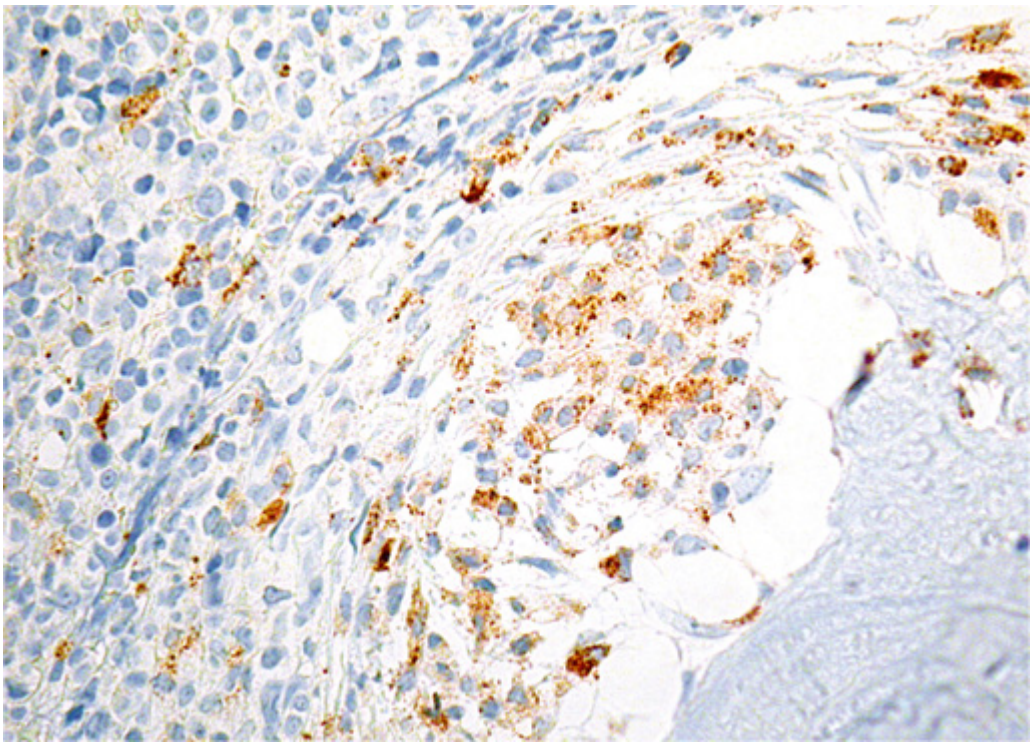

FIGURE 49-19 Systemic mastocytosis with an associated hematologic neoplasm. Immunostaining for tryptase in this case of acute myeloid leukemia reveals a focal paratrabecular infiltrate of mast cells, diagnostic of concurrent systemic mastocytosis. Sequencing analysis revealed *RUNX1* R162K mutation with a variant allele frequency (VAF) of 81% and a *KIT* D816V mutation with a VAF of 41%, indicating multimutational high VAF-burden disease and suggesting that the *KIT* D816V mutation was acquired after the *RUNX1* R162K mutation and played a role as "phenotype modifier," paving the way to accompanying mast cell differentiation.

Immunophenotype and Genetics

Immunostaining for tryptase, KIT/CD117, CD25, and CD30 is usually sufficient to establish the diagnosis of SM in the setting of SM-AMN/AHN. Regarding the AMN, appropriate immunostainings (e.g., for CD14, CD34, IRF8,[178] and myeloperoxidase, etc.) are indicated.

The *KIT* D816V mutation is found in 60% to 94% of patients and is usually detected in the SM component but also in the AMN component.[12,13] Especially in SM-CMML, *KIT* mutations have been detected in CMML cells in 89% of cases, suggesting a common (MC/monocytic) precursor cell. In SM-AML, except for AML t(8;21)(q22;q22.1)/*RUNX1*::*RUNX1T1,* and SM-MPN, the frequency of a *KIT* mutation in the AMN component is lower (30% and 20%, respectively).[46,47,126] Non-*KIT* mutations are very frequent in SM-AMN; they are often observable at higher VAFs, indicating the *KIT* D816V mutation may act as a modifier toward MC differentiation of an initially non-*KIT* mutated background precursor cell.[82,96] It should be noted that the mutational profile differs between ISM-AMN and ASM-AMN or MCL-AMN. In the former, non-*KIT* mutations predominantly involve *JAK2, ETV6, U2AF1, EZH2,* and/or *SF3B1*; in ASM-AMN or MCL-AMN, non-*KIT* mutations mainly involve *TET2, SRSF2, ASXL1, RUNX1, N/KRAS,* and *IDH2*.[97]

Postulated Cell of Origin

The postulated cell of origin: pluripotent hematopoietic stem and progenitor cells.

Clinical Course

In most patients, the clinical course and prognosis are dominated by the AMN/AHN, not by the SM. However, if the SM corresponds to ASM or MCL, SM will be prognostically decisive. Both the SM component and the AMN/AHN component of the disease need to be classified accordingly. The presence of an *ASXL1* or *SRSF2* mutation and the number of mutations in the *SRSF2/ASXL1/RUNX1* panel seem to be independent prognostic factors, negatively affecting overall survival.[12,13] Modern midostaurin, polychemotherapy, stem cell transplantation, and especially avapritinib-based/containing regimens have significantly improved the outcomes in patients with SM-AMN.[56,93,179]

Differential Diagnosis

SM-AMN must be distinguished from non-MC myeloid tumors with signs of MC differentiation (e.g., tryptase-positive AML) and from MDS/AML with prominent involvement of the MC lineage, as seen in MML.[105,118,147,180] MC differentiation in AML is associated with tryptase expression in otherwise morphologically unremarkable blast cells, which sometimes form clusters, without the typical focal MC infiltrates of SM. In MML, there is a diffuse but variable increase in tryptase-expressing metachromatic cells (metachromatic blasts) that are often highly atypical, may express CD34, an antigen never expressed by MCs, and are almost always CD25 negative. As in tryptase-positive AML, focal compact MC infiltrates are not seen in MML.

Aggressive Systemic Mastocytosis

Definition

ASM is a rare subtype of SM that exhibits the clinical characteristics of a high-grade hematologic neoplasm and signs of severe organ damage caused by MC infiltration, usually involving the BM and extramedullary organs, thus displaying ≥1 so-called “C finding.”

Epidemiology

ASM is much less common than ISM and SM-AMN/AHN, accounting for about 5% of all SM cases.

Clinical Features

ASM is characterized by an aggressive clinical course with marked MC infiltration of various organs and tissues, including the BM, liver, spleen, GI tract mucosa, lymph nodes and/or skeleton. Skin lesions are present in <50% of cases. The total MC burden is high, with corresponding organomegaly (usually hepatomegaly and/or splenomegaly, occasionally lymphadenopathy) and signs of impaired organ function (e.g., cytopenia, ascites, portal hypertension, hypersplenism, malabsorption caused by GI tract MS infiltration, large osteolysis with or without pathologic fracture) that are all summarized as so-called “C findings” (indicative of organ damage).[55,181,182] Serum tryptase levels are almost always markedly elevated.

Morphology

The BM is hypercellular, with focal and diffuse infiltration by atypical, hypogranular, nonmetachromatic MCs that usually show prominent spindling (**Fig. 49-20**). However, a subset of these cells may also be quite immature. There may be slight atypia of blood cell precursors or signs of myeloproliferation. An AMN/AHN may be

present, which can become more evident after treatment of the ASM, and the disease should be then reclassified accordingly (SM-AMN/AHN). ASM-t, in which progression to MCL is ongoing, will usually display >5% MCs on BM smears, and as soon as the percentage is 20%, the diagnosis of a secondary MCL should be established.[105]

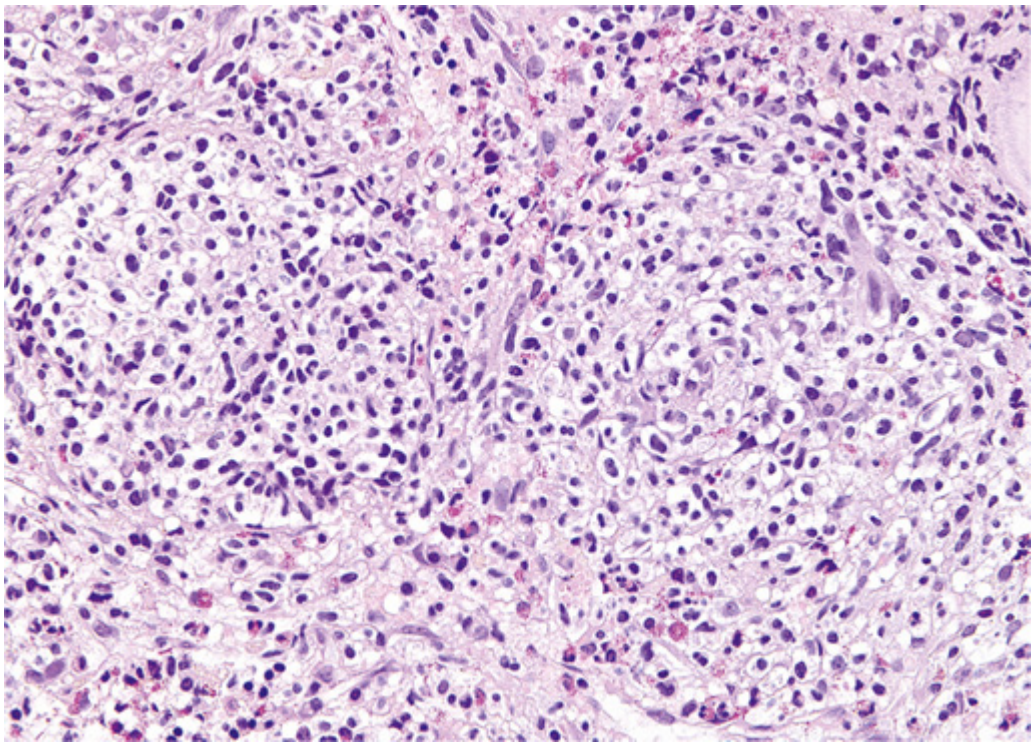

FIGURE 49-20 Aggressive systemic mastocytosis infiltrating the bone marrow. Note the cytologic atypia of mast cells. Sequencing analysis revealed *ASXL1* S1028fs with a variant allele frequency (VAF) of 17%, CKIT: *KIT* D816V with a VAF of 15%, *RUNX1* S322fs with a VAF of 7%, *SRSF2* P95L with a VAF of 40%, *TET2* H1904R with a VAF of 44%, and Y1245fs with a VAF of 44%, indicating multimutational high VAF-burden disease. This suggests the *TET2* and *SRSF2* mutations were founding, the *ASXL1* mutation was disease progression mutation, and the *CKIT* mutation was a “phenotype modifier” mutation.

A distinct variant of ASM with clinical features mimicking generalized malignant lymphoma has been termed lymphadenopathic mastocytosis with eosinophilia. In contrast to classic ASM, this condition is associated with generalized lymphadenopathy and marked blood eosinophilia.[183]

Immunophenotype and Genetics

The MCs in ASM are always tryptase positive and usually co-express CD25, CD30, and KIT/CD117. In a proportion of cases, the MCs also express CD2, whereas chymase is relatively rarely detected and is usually not expressed by all MCs in a given case.

The *KIT* D816V mutation is detected in approximately 80% of cases. Molecular studies in ASM brought evidence for the presence of multilineage involvement by the *KIT* mutations, often accompanied by the presence of additional "myeloid" mutations.[55,82,153,184,185] Thus, ASM and SM-AMN are genetically very close, being multimutational and high *KIT* mutational burden diseases, ASM not reaching criteria for a straightforward diagnosis of an additional myeloid neoplasm.

Postulated Cell of Origin

The postulated cell of origin is a hematopoietic MC-committed stem cell.

Clinical Course

The prognosis of ASM is worse than that of ISM or SSM. The median overall survival of patients with ASM is approximately 4.5 years.[153] As mentioned, patients with ASM-t have a very poor prognosis.[105]

These patients rapidly progress to MCL, which is otherwise generally observable in a sixth of individuals affected by ASM.[105,185,186]

Differential Diagnosis

ASM must be differentiated from SSM (C findings are missing), SM-AMN, and particularly aleukemic MCL (MC count <20% in BM smears excludes MCL and favors ASM).[12]

Mast Cell Leukemia

Definition

MCL is a highly malignant neoplasm meeting the criteria of SM that is accompanied by a significant increase of atypical MCs in the BM smears (>20% of all cells in BM smears). In the ICC 2022,[12] the diagnosis does not solely rely on the aspirate and, in the presence of a suboptimal aspirate (dry tap), a BM biopsy showing a diffuse MC infiltration of immature atypical MCs (e.g., immature bilobed forms and multinucleated or bizarre MCs) in the proper clinical context can be used to support a diagnosis of MCL, which is in contrast to previous WHO proposals and the proposals of the consensus group.[39,105] This is of major practical importance, as especially dry taps apply to many diagnostically challenging cases.

MCL can be divided in a leukemic form, defined by ≥10% MCs of all leukocytes in peripheral blood, and the more frequent aleukemic form with <10% MCs.[39,105] Although it is still recommended to document the presence of circulating MCs, their presence no longer indicates a separate subcategory because data show that any circulating MCs are linked to poorer prognosis of MCL.[56] Finally, MCL can be divided into acute MCL, defined by signs of MCL-

induced organ damage, and chronic MCL, in which no signs of MCL-induced organ damage are found.[39,105]

Epidemiology

MCL is extremely uncommon and probably represents the rarest form of leukemia in humans. A few hundred well-documented cases have been reported.[51-56,187]

Clinical Features

Patients with MCL usually present with signs of an acute leukemia, including prominent cytopenia, and often signs of organ damage. If this is not the case and no other signs of SM-related organ damage are noted (i.e., lacking C findings) but the criteria of MCL are fulfilled, the final diagnosis of chronic MCL should be rendered.[39,56,105] The typical skin lesions of MPCM are absent, but disseminated leukemic skin infiltrates have occasionally been described, and signs of MC activation are rarely found. Owing to the large MC burden, serum tryptase levels are markedly or even excessively elevated, and mediator-related symptoms regularly occur. Most patients with MCL die within 1 year of diagnosis unless treated with polychemotherapy and stem cell transplantation. More prolonged survival is observed in the rare form of chronic MCL.[188]

Morphology

As in most cases of acute leukemia, the BM in MCL usually shows a dense, diffuse-compact infiltration pattern, with subtotal displacement of fat cells and normal hematopoiesis (**Fig. 49-21**). Abundant, highly atypical, often round MCs are seen in BM and blood smears in most cases. These MCs are often hypogranular and

exhibit immature blast-like morphology with monocytoid or even lobulated nuclei (metachromatic blasts). Metachromatically granulated blast cells are also recorded in patients with MCL. In rare cases, the MCs exhibit a mature phenotype, with round nuclei and an abundance of metachromatic granules. Fibrosis is typically less than that seen in ASM.

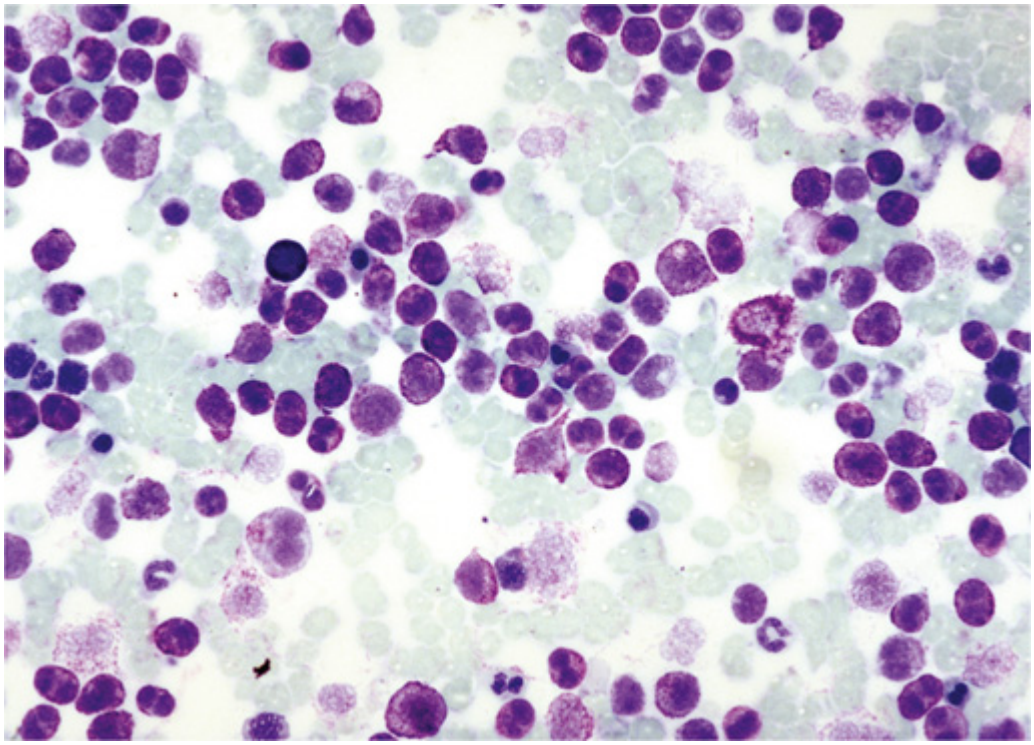

FIGURE 49-21 Mast cell leukemia. This bone marrow smear shows an extremely pronounced increase in atypical mast cells containing varying amounts of metachromatic granules. The mast cells constitute more than 90% of all the nucleated cells. A large number of circulating mast cells is also present (compare with **Fig. 49-4**).

Immunophenotype and Genetics

Leukemic cells in MCL express tryptase, CD25, KIT/CD117, and often also CD30.[189] Like the neoplastic MCs in all other types of SM, they may also co-express CD2 but are more frequently CD2 negative.

The *KIT* D816V mutation is found in 50% to 70% of cases. Other *KIT* mutations and wild-type *KIT* are each observable in 10% to 20%. Non-*KIT* mutations are frequent and recurrently involve *TET2, SF3B1, SRSF2, ASXL1, BRAF, KRAS,* and *NRAS*.[55,56,190]

Postulated Cell of Origin

The postulated cell of origin is an MC-committed hematopoietic stem or progenitor cell.[60]

Clinical Course

MCL may occur as primary (de novo) or secondary, evolving from an anteceding MC neoplasm, mainly SM-AMN or ASM.[55,190] MCL almost always behaves aggressively. At the time of this writing, the median survival time was 1.6 years (without intensive therapy). The prognosis seems to be better in the very few examples of chronic MCL, in *KIT* D816V mutated cases, in patients treated with midostaurin or avapritinib, and in patients without abnormal karyotype with primary MCL.[56] Exceptional patients with complete remission and long-term survival after polychemotherapy and allogenic stem cell transplantation have been reported as well.[179] Impressive responses have also been reported with application of the KIT D816V-specific tyrosine kinase inhibitor avapritinib.[92]

Differential Diagnosis

The differential diagnosis includes basophilic leukemia, SM-AMN, and MML. The aleukemic variant of MCL has to be discriminated from ASM and ASM-AHN and is accounted for in the ICC 2022.

Mast Cell Sarcoma

Definition

MCS is even rarer than MCL. It presents as local, sarcomatous, destructive tumor of highly atypical MCs, initially without clinical signs of dissemination or generalization.

Epidemiology

Few well-documented cases of MCS have been described, and 10 more have been more recently reported, summarizing the up-to-date publications.[116,191-194] It is interesting that, in addition to bones (skull, tibia), involved sites were not the lymphoreticular tissues commonly affected by mastocytosis but instead the larynx, colon, dura, uterus, small intestine, inner lip, pelvis, skin/soft tissue of the ankle, spleen, and liver. The sex distribution is nearly equal, and there is a huge variation of age (range 1–77 years, median 39).[116]

Clinical Features

MCS presents with signs of local tumor growth that are largely non-specific, but in all patients reported, an aggressive growth and expansion of the local tumor has been described. As per definition, MCS is a strictly localized tumor, but secondary dissemination and progression to MCL is often seen. When an antecedent or accompanying SM is found, the disease should not be called MCS but should be regarded as MCS-like progression in SM.[55,116,195] It is remarkable that, in three MCS cases, the patients had a history of a

germ cell tumor, and in one, the *KIT* D579del mutation was shared between the MCS and the antecedent mediastinal yolk sack tumor.[116,196] Though based on the small number of cases described, it appears that MCS tends to rapidly disseminate and transform to MCL.

Morphology

MCS is one of the most aggressive neoplasms within the spectrum of MC disorders and is characterized by atypical hypogranular tumor cells that often exhibit bizarre nuclei and prominent nucleoli, mimicking a high-grade sarcoma at first glance (**Fig. 49-22**). The morphology of these cells mostly resembles that seen in MCL.

Immunophenotype and Genetics

The tumor cells express tryptase and KIT/CD117.

The majority of MCSs are *KIT* wild type. The *KIT* D816V mutation is reported in <10% of cases, and a fifth seems to display other *KIT* mutations, including L799F, N822Y, N822K, V560G, D419del, and D579del.[116,196]

Postulated Cell of Origin

The postulated cell of origin is an MC-committed stem/precursor cell.

Clinical Course

MCS follows a highly aggressive course with a median survival of 24 months.[116,191-196] Most patients progress to MCL within a short time. Some may temporally respond to a KIT-targeting drug like imatinib.[197,198] The survival time is very short in almost all cases.

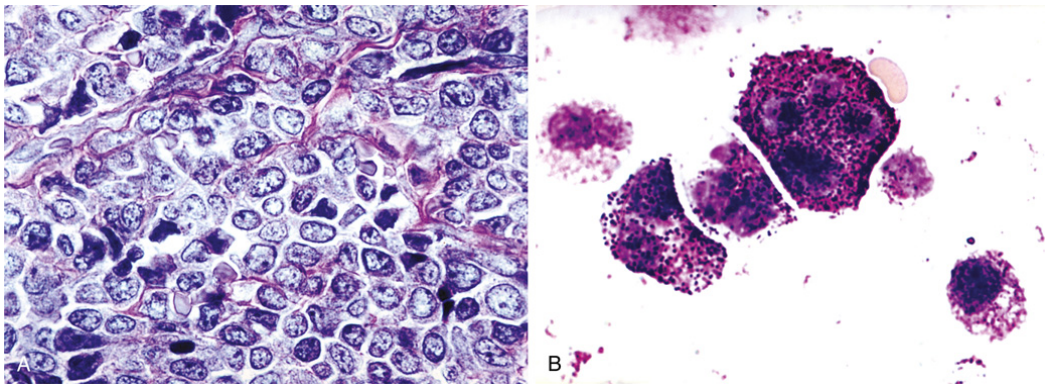

FIGURE 49-22 **Mast cell sarcoma.A,** The histopathologic picture is that of a cellular pleomorphic tumor with only a mild desmoplastic reaction. Even with the meticulous evaluation of Giemsa-stained sections, no metachromatic granules can be detected. Because most of the tumor cells strongly expressed chloroacetate esterase, CD117, and tryptase, a diagnosis of mast cell sarcoma was established. **B,** Touch preparations also provide the correct diagnosis. With this technique, the pleomorphic, sometimes multinucleated tumor cells can be seen to contain an abundance of metachromatic granules; these were not detectable in routinely processed specimens, presumably because of water solubility. The granules of normal basophils are water soluble, as may be the case for highly malignant mast cell tumors (mast cell leukemia and mast cell sarcoma).

Differential Diagnosis

The differential diagnosis includes high-grade round cell sarcomas, histiocytic sarcoma, Langerhans cell sarcoma, ALK-negative anaplastic large cell lymphoma, myeloid sarcoma, and melanoma. The expression of tryptase by MCS and its negativity for CD1a, langerin, S100, melanocytic markers, and myeloperoxidase clearly distinguish it from these listed neoplasms.[116,199] A diagnosis of extracutaneous mastocytoma, which exhibits monomorphic, round, well-differentiated, strongly metachromatic tumor cells, is easy to exclude. Fibromastocytic tumors, which are extremely rare, should also be considered in the differential diagnosis.[200]

Extracutaneous Mastocytoma

Definition

Extracutaneous mastocytoma (ECM) is a benign localized tumor consisting of mature-appearing MCs, with no signs of systemic involvement. Although not included in the current classifications, ECM is discussed herein.

Epidemiology

Unlike CM, ECM is extremely rare and has been found predominantly in the lung and occasionally in the head, neck, and stomach.[55,201,202]

Clinical Features

In ECM, the clinical features are those of an organ tumor that may appear intensively yellowish on macroscopic examination,[55] with no specific clinical signs.

Morphology

In contrast to MCS, ECM exhibits relatively monomorphic, strongly metachromatic, round MCs that are easily recognizable when basic dyes such as Giemsa and toluidine blue are applied.

Immunophenotype

The tumor cells express tryptase and KIT/CD117.

Postulated Cell of Origin

The postulated cell of origin is an MC-committed precursor.

Clinical Course

The clinical course is that of a benign tumor, with complete remission after resection. Progression to an aggressive disease has not been reported, yet one patient with gastric ECM was diagnosed with ISM within disease course.[53]

Differential Diagnosis

The major differential diagnosis of ECM is local MC hyperplasia. Another differential diagnosis may be ISM. Therefore, the diagnosis of ECM should be established only after a careful and thorough investigation of the adjacent tissue and definitive exclusion of all other SM criteria. In some instances, the hematopathologist may ask for another organ biopsy (to detect a second infiltrate) before making the final diagnosis of ECM. Because ECM consists of sheets of well-differentiated metachromatic MCs, it can be easily distinguished from MCS and soft tissue sarcomas. In H&E (hematoxylin and eosin) stains, the MCs may have a plasmacytoid appearance, initially suggesting a diagnosis of plasma cell granuloma. GIST, also at extra

GI sites, should always be taken into consideration and excluded by staining for tryptase and DOG1.

Pearls and Pitfalls

Pearls

- A multifocal, compact tryptase and/or KIT/CD117-positive mast cell infiltrate in internal organs, such as bone marrow or spleen, is the major diagnostic criterion for SM.
- Mast cells exhibiting a spindle shape, co-expression of CD2, CD25, and/or CD30, or any activating mutation of *KIT* are strongly indicative of SM.
- The most common variants of mastocytosis—CM and ISM—usually have a benign clinical course.
- SM with an associated myeloid neoplasm is distinctive among hematologic neoplasms.
- Indolent mast cell neoplasms are unimutational disorders with single (mast cell) lineage involvement by a driver *KIT* mutation, but advanced mast cell neoplasms are multimutational disorders with multilineage hematopoietic involvement in which *KIT* mutations usually play a role as "phenotype modifier," paving the way to mast cell differentiation.

Pitfalls

- Mastocytosis must be distinguished from a variety of rare hematopoietic and non-hematopoietic disorders, especially myelomastocytic neoplasms (tryptase-positive AML, MML), myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions, chronic eosinophilic and basophilic leukemias, lymphomas, sarcomas, gastrointestinal stromal tumors, and melanomas.
- Mast cells in reactive and neoplastic states usually co-express tryptase and CD117/KIT; cells expressing only tryptase (neoplastic basophils) or only CD117 (hematopoietic progenitor cells and/or others) must not be termed mast cells.
- Detection of *KIT* mutations has prime importance in mastocytosis and must by assessed by sensitive methods, as these mutations represent a minor diagnostic criterion of SM; if assessed in a quantitative manner they are of significant prognostic value and are major predictors of targeted drug sensitivities.

Chapter 50: Eosinophilia, Chronic Eosinophilic Leukemia, Not Otherwise Specified, and Myeloid/Lymphoid Neoplasms With Eosinophilia and Tyrosine Kinase Gene Fusions

Kaaren K. Reichard, Sa A. Wang, Daniel A. Arber, and Attilio Orazi

OUTLINE

Overview

Introduction

Classification

Clinical Presentation

Approach To Diagnosis

Myeloid/Lymphoid Neoplasms with Eosinophilia and Rearrangements Of PDGFRA, PDGFRB, FGFR1, FLT3, OR JAK2 or with ETV6::ABL1

Overview

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of PDGFRA

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of PDGFRB

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of FGFR1

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of JAK2

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of FLT3

Myeloid Neoplasms With Eosinophilia and ETV6::ABL1

CEL, NOS, IHE/IHES, and other Rare Reported Genetic Alterations Associated with Clonal Eosinophilia

Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL, NOS)

Idiopathic Hypereosinophilia/Hypereosinophilic Syndrome (iHE/iHES)

Conclusion

Overview

Eosinophilia encompasses a complex group of disorders of diverse etiology for which there are many tools available for the workup and diagnosis. This chapter addresses the clinical, pathologic, and genetic features of the International Consensus Conference (ICC) category of myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions (M/LN-eo-TK), chronic eosinophilic leukemia, not otherwise specified (CEL, NOS), and idiopathic hypereosinophilia (iHE)/idiopathic hypereosinophilic syndrome (iHES).[1-11]

This chapter focuses on the workup and diagnosis of eosinophilic disorders. First, a reasonable yet comprehensive approach to the initial workup of hypereosinophilic disorders is presented, with specific attention paid to the role of morphologic and laboratory features and proper use of ancillary testing, particularly genetic tools. Second, specific clinicopathologic aspects of the ICC categories of M/LN-eo-TK (e.g., myeloid/lymphoid neoplasms with eosinophilia and *PDGFRA, PDGFRB, FGFR1, JAK2,* or *FLT3* rearrangement or *ETV6*::*ABL1*), CEL, NOS, and iHE/iHES are discussed.[1-11] It is beyond the scope of this chapter to provide a detailed description of

other entities often in the differential diagnosis with eosinophilia, which are covered in other chapters of this book (chronic myeloid leukemia [CML], see **Chapter 47**; acute myeloid leukemia [AML] with inv[16], see **Chapter 46**; systemic mastocytosis, see **Chapter 49**). It should also be mentioned that pediatric/constitutional/immunodeficiency disorders that are associated with eosinophilia are also beyond the scope of this chapter.

Introduction

Eosinophilia can be caused by or associated with a complex group of disorders. Given the diversity of the underlying etiology, the initial approach is to organize eosinophilic conditions into primary (clonal) and secondary (reactive) categories for further discussion (see **Box 50-1** for a non-exhaustive listing of etiologies).[12-15] As can be seen in **Box 50-1**, the underlying causes of an eosinophilic disorder may range from drug/medication exposure, infection, and autoimmune conditions to a malignancy wherein the eosinophilia is a reactive consequence or a primary clonal proliferation of eosinophils. The cause of eosinophilia is best identified by the patient's history, clinical presentation, and specific laboratory testing. Reactive eosinophils typically demonstrate normal eosinophilic cytology; however, abnormal features such as hypogranulation, eccentric location of granules within the cytoplasm, hyposegmentation, and cytoplasmic vacuoles may be seen in some eosinophils in reactive expansions (**Fig. 50-1**).

By far, the nonclonal forms of eosinophilia greatly outweigh the clonal forms. For example, allergy, drug/medication, hypersensitivity

reactions, and infection are common causes of eosinophilia. Given the breadth of possible causes of eosinophilia, one can appreciate the variety of testing options that should or should not be undertaken depending on the features of an individual case. Depending on the patient's clinical condition, a proper and timely workup of such disorders is crucial because of the clinical potential for eosinophilic organ infiltration with subsequent tissue damage (hypereosinophilic syndrome).[15] iHES can be associated with significant morbidity and mortality, and prompt delineation of a definitive and treatable etiology, if possible, is desired.

Box 50-1 Etiologies Underlying Eosinophilia

Secondary (Reactive Eosinophilia)

Allergic diseases: Asthma, allergic rhinitis, atopic dermatitis, drug hypersensitivity
Infections: Helminths, parasites, protozoans, fungi, viruses
Neoplastic disorders: Solid tumors, lymphoid malignancies (e.g., lymphoblastic leukemia, classic Hodgkin lymphoma, B-cell and T-cell lymphomas)
Immunologic disorders: Immunodeficiencies, autoimmune and other connective tissue disorders
Eosinophilic disorders: Eosinophilic granulomatosis with polyangiitis, eosinophilic gastrointestinal disorders
Other: Radiation exposure, cholesterol emboli, hypoadrenalism, IL-2 therapy

Primary (Clonal Eosinophilia); International Consensus Classification (ICC)-Recognized Entities

- Myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions (myeloid/lymphoid neoplasm with *PDGFRA* rearrangement, myeloid/lymphoid neoplasm with *PDGFRB* rearrangement, myeloid/lymphoid neoplasm with *FGFR1* rearrangement, myeloid/lymphoid neoplasm with *JAK2* rearrangement, myeloid/lymphoid neoplasm with *FLT3* rearrangement, and myeloid/lymphoid neoplasm with *ETV6*::*ABL1*)
- Myeloproliferative neoplasms (particularly chronic eosinophilic leukemia, not otherwise specified; chronic myeloid leukemia with eosinophilia)
- Acute myeloid leukemia, particularly AML with inv(16)
- Systemic mastocytosis (the eosinophils are not clonal in all cases)
- Myelodysplastic syndromes (rare)
- Chronic myelomonocytic leukemia (rare)

Eosinophilia is defined by an absolute eosinophil count (AEC) that exceeds 0.5 × 10^9/L or relative peripheral blood eosinophilia of >6% eosinophils on the differential count.[15-18] It may further be designated as mild (0.5–1.49 × 10^9/L), moderate (1.5–5.0 × 10^9/L), or severe (>5 × 10^9/L). The AEC is calculated as follows: white blood cell (WBC) count × 10^9/L × percentage of eosinophils = AEC (eosinophils × 10^9/L).[16,17]

Classification

The classification of eosinophilic diseases should be specific and reference whether it is reactive or clonal, when possible. For example, it should be stated that a patient has reactive eosinophilia in the setting of a known medication, or for clonal eosinophilic disorders, the diagnosis should adhere to the most recent classification scheme such as the International Consensus Conference.[3,5] **Box 50-1** lists the ICC entities that may be associated with clonal eosinophilia.

Clinical Presentation

It should be noted that the AEC neither predicts the underlying etiology nor the potential clinical severity of the disease. Though an extremely increased AEC (>20–30 × 10^9/L) is uncommon in allergic and asthmatic conditions and may help point toward a neoplastic disorder, this is insufficient, by itself, for a malignant diagnosis. Similarly, the AEC cannot predict the degree, if any, of eosinophil-related end organ damage. For example, a patient with mild eosinophilia may experience significant organ damage/dysfunction. Organ involvement/damage requires clinical, imaging, and laboratory evaluation.

Given the diverse underlying causes of eosinophilia and involvement of various organs/tissues by eosinophilia, patients may present with different symptoms and show different signs, such as constitutional symptoms; skin rash/cutaneous lesions; gastrointestinal, respiratory/pulmonary, cardiac, muscular/joint, endocrine, and/or central nervous system involvement; or newly emerging lymphadenopathy, hepatomegaly, or splenomegaly.[6,15-19] Although less common than dermatologic, pulmonary, and

gastrointestinal manifestations, cardiac failure due to endocardial damage and subsequent fibrosis and valvular insufficiency may result in significant morbidity and mortality. Similarly, central nervous system involvement is uncommon but associated with a grave outcome. The clinical presentation and prognosis of clonal eosinophilia is very depending on the underlying hematopoietic neoplasm; and patients often have cytopenia(s) and/or cytosis with or without increased blasts. Eosinophilia-associated organ damage may occur in around 30% to 40% of patients with clonal eosinophilia.

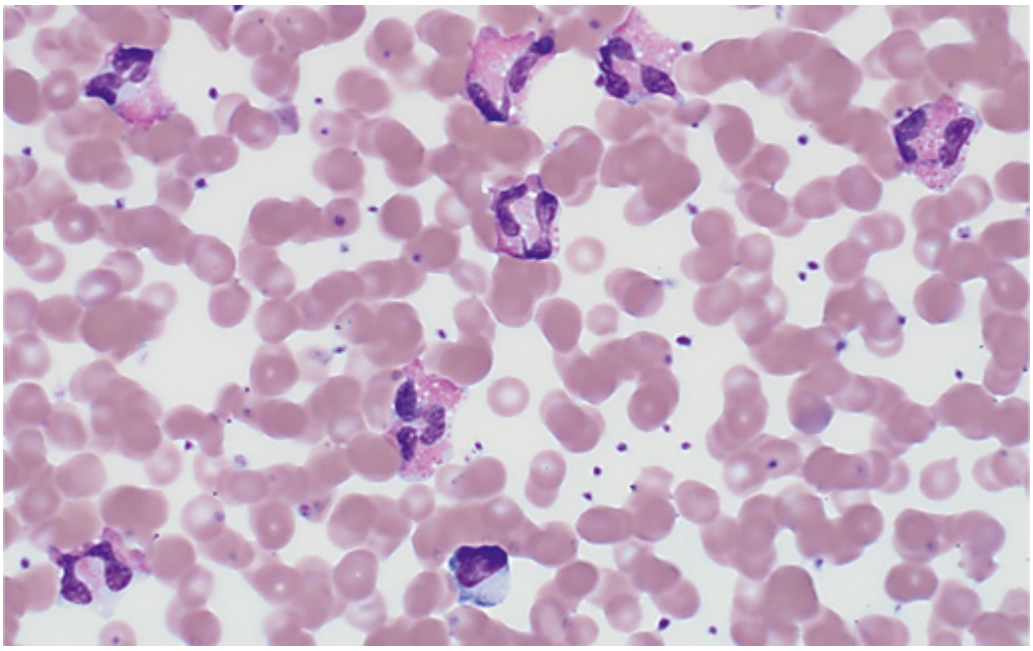

FIGURE 50-1 Reactive eosinophilia. Peripheral blood smear from a 55-year-old male with an absolute eosinophil count of 10.3 × 10^9/L discovered incidentally after taking antibiotics for an upper respiratory infection. Though many of the eosinophils demonstrate normal cytologic features, several exhibit vacuolization, partial degranulation, and eccentric localization of granules within the cytoplasm (1000× magnification; Wright-Giemsa).

Approach To Diagnosis

A reasonable initial approach to the diagnosis in a case of unexplained eosinophilia is to exclude secondary causes, assuming the patient is clinically stable.[13,20-25] Secondary eosinophilia has

many causes (**Box 50-1**) and is much more common than primary eosinophilia. The diagnostic workup often involves consultation with multiple medical specialties including allergy, hematology, pulmonary, infectious disease, rheumatology, and gastroenterology. Specific entities such as drug/medication reactions, hypersensitivity, and pulmonary eosinophilic disorders (e.g., chronic eosinophilic pneumonia, eosinophilic granulomatosis with polyangiitis) are typically diagnosed in the appropriate clinical, radiologic, and pathologic context. Underlying malignancies, such as lymphoma and solid tumor, may also be associated with reactive eosinophilia. In these cases, the eosinophilia results from the production and release of cytokines such as interleukin (IL)-3 and IL-5 by the tumor cells, which promote eosinophil proliferation. Evaluation for underlying infectious conditions or immunologic/immunodeficiency disorders would be predicated on the clinical presentation and history. Depending on the clinical scenario, additional radiologic, laboratory, and/or pathologic testing may be necessary.

If secondary/reactive causes for eosinophilia have been excluded, it is appropriate to begin evaluation for a primary clonal eosinophilia (**Fig. 50-2**). The pace and/or extent of the diagnostic workup may be influenced by the clinical stability of the patient and where the patient is seeking care. In the community setting, an exhaustive clinical investigation into the etiology of the eosinophilia may not be performed. In contrast, a medical center/institution that specializes in eosinophilic disorders may provide a more in-depth and specialized evaluation. In the case of a clinically unstable patient, a systematic and progressive algorithmic approach will not be possible. In such situations, it is prudent to obtain as many

“pretreatment” tests (e.g., laboratory studies, tissue biopsies, peripheral blood, and bone marrow samples) as possible given the effects treatment may have on subsequent diagnostic evaluation.

The workup will vary (less to more extensive) depending on the clinical, laboratory, radiologic, and/or morphologic features.[13-15,20-26] If it is determined from a clinical perspective that a peripheral blood/bone marrow sample should be obtained, the morphology becomes a critical driver for next-step(s) decision making. For example, the workup of a patient with “eosinophilia” but in the context of morphologic features otherwise consistent with CML may not require extensive immunophenotypic and/or genetic testing outside of the context of demonstrating presence of the Philadelphia chromosome/*BCR*::*ABL1* fusion. On the other hand, a patient who lacks features that may be diagnostic of a particular entity may require additional flow cytometric, immunohistochemical, and genetic testing (**Fig. 50-2**). Several pathology-focused, algorithmic approaches have been published with roughly similar strategies that may very slightly among institutions based on patient case types, clinical trial availability, and access to research.[6,20-25] In general, bone marrow specimens should be submitted for flow cytometry (exclude T-cell lymphoma or lymphocytic variant of hypereosinophilic syndrome), immunohistochemistry for tryptase, CD117, and CD25 to evaluate for mast cells/mastocytosis, fluorescence in situ hybridization (FISH) or reverse transcription polymerase chain reaction (RT-PCR) for the *FIP1L1*::*PDGFRA* fusion (typically cytogenetically cryptic), and karyotype to assess for CEL, NOS or detect a possible recurring genetic abnormality (4q12 *[PDGFRA]*, 5q32 *[PDGFRB]*, 8p11.23 *[FGFR1]*, 9p24.1 *[JAK2]*,

13q12.2 *[FLT3]* or 9q34.12 *[ABL]*), which can be further proven by FISH and/or molecular studies. Also, given the increasing recognition and prevalence of molecular genetic abnormalities in eosinophilia that are not detected by FISH or cytogenetics, submission of a sample for DNA and RNA extract and hold should be considered. This may be important in the diagnostic workup if the aforementioned studies do not reveal a specific diagnosis and there remains clinical and/or pathologic concern for a clonal eosinophilic disorder. If next generation sequencing (NGS) studies are performed, it is important to remember that specific recurring abnormalities in primary clonal eosinophilia have yet to be unveiled, and one should be careful to distinguish an identified mutation diagnostic of CEL, NOS from one diagnostic of clonal hematopoiesis of indeterminate potential (CHIP)/clonal cytopenias of uncertain significance. In the ICC, bone marrow morphology has been incorporated in the diagnostic criteria for CEL, NOS.

The identification of the specific tyrosine kinase fusion gene is critical for diagnosis and subsequent treatment, as tyrosine kinase inhibitors (TKIs) have significantly improved the treatment and outcome of patients with *PDGFRA* and *PDGFRB* gene rearrangements[3-5] and are beneficial for patients with *ETV6*::*ABL1*. Other patients with *FLT3* and/or *JAK2* rearrangements may benefit from FLT3 and JAK2 inhibitors, respectively. See the discussion of that particular entity for more detailed information.

Myeloid/Lymphoid Neoplasms with Eosinophilia and Rearrangements Of *PDGFRA, PDGFRB, FGFR1, FLT3,* OR *JAK2* or with *ETV6*::*ABL1*

Overview

In 2008, the World Health Organization (WHO) classification introduced a new category of primary clonal eosinophilic conditions that result from tyrosine kinase gene fusions. This new category was termed “myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRA, PDGFRB,* or *FGFR1*.” In 2017, the WHO classification was revised to add myeloid/lymphoid neoplasms with *PCM1-JAK2* as a provisional entity.[1,2] In the ICC, additional rearrangements involving other tyrosine kinase fusion genes, *FLT3* and *ETV6*::*ABL1,* that may present as myeloid/lymphoid neoplasms with eosinophilia have been recognized and are now formally a part of the classification.[3,5,9,11] The 2022 name change to “myeloid/lymphoid neoplasms with eosinophilia and tyrosine kinase gene fusions” reflects the importance of consequent constitutive tyrosine kinase activity and subsequent therapeutic implications.[3] A few cases of rearrangement of *LYN*[27] have been reported to bear features resembling M/LN-eo-TK; however, more data are needed to understand the disease spectrum and response to TKI before being formally included in the category. Other potential members are *FGFR2* and *KIT* rearrangement.

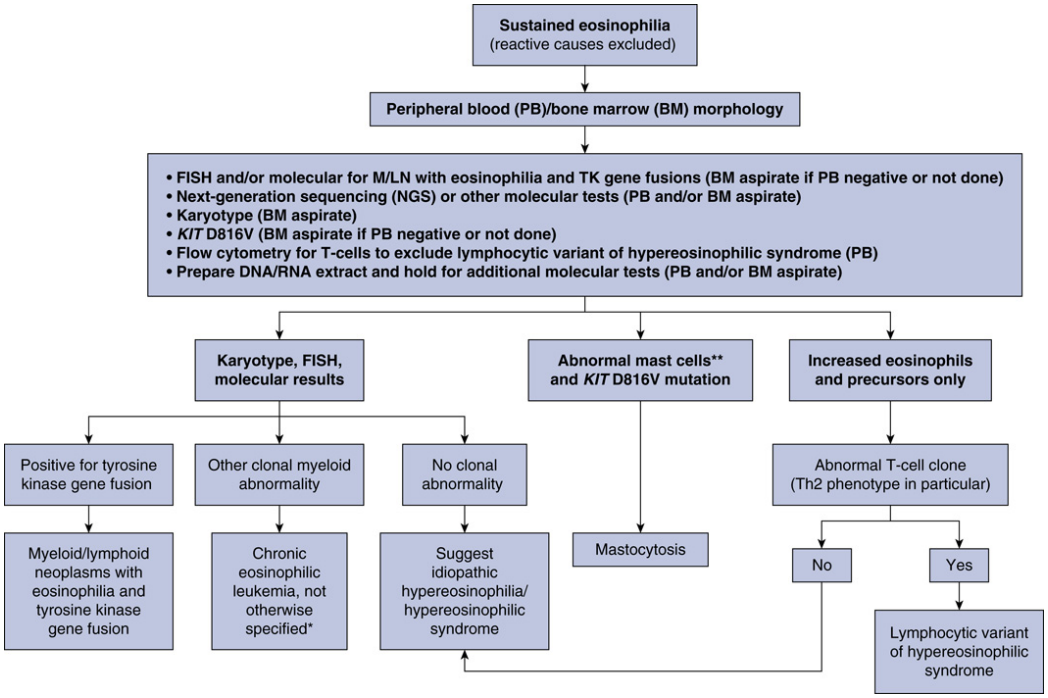

FIGURE 50-2 An algorithmic approach to the workup and diagnosis of unexplained cases of eosinophilia that undergo bone marrow examination. ∗BM typically shows additional morphologic abnormalities (e.g., megakaryocytic dysplasia). ∗∗Abnormal morphology (mature spindled hypogranular; promastocytes; metachromatic blasts); abnormal immunophenotype (expression of CD2 and/or CD25, CD30). *FISH,* Fluorescence in situ hybridization; *M/LN,* myeloid/lymphoid neoplasm; *TK,* tyrosine kinase.

These entities share some clinical similarities, including frequent constitutional symptoms such as fatigue, weight loss, pruritis, and hepatosplenomegaly. Eosinophilic end organ damage/dysfunction has been reported in around 30% to 40% of patients and may involve

the heart, lungs, and other organs. It is now well recognized that this group of disorders presents as a variety of different disease phenotypes, including chronic myeloid neoplasm (CMN), blast phase CMN, lymphoblastic lymphoma/myeloid sarcoma in an extramedullary site, complex presentation with CMN in bone marrow, and extramedullary lymphoblastic lymphoma. Eosinophilia is frequently but not invariably present. These features are further elaborated upon in the individual diagnostic sections. Given the variety of potential presentations, a high index of suspicion and knowledge of the heterogeneity of these disorders is necessary for proper workup, diagnosis, and treatment.[28]

A list of the known partner genes in the fusions involving *PDGFRA, PDGFRB, FGFR1, JAK2, FLT3,* and *ABL1* are listed in **Box 50-2**.

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *PDGFRA*

Definition

A myeloid and/or lymphoid neoplasm that has a demonstrable rearrangement of the *PDGFRA* gene or, less commonly, an activating mutation leading to constitutive activation of tyrosine kinase. In the case of de novo presentation as B-lymphoblastic or T-lymphoblastic leukemia/lymphoma, if the *PDGFRA* rearrangement is not present in background myeloid cells, the best diagnosis is Philadelphia-like B-lymphoblastic leukemia (B-ALL) or de novo T-lymphoblastic leukemia (T-ALL) with *PDGFRA* rearrangement.

---

* Common fusion gene partners are underlined.

Genetics

The majority of these cases (approximately 90%) present as CMN and carry the *FIP1L1*::*PDGFRA* fusion. A minority of cases will show alternative gene partners (**Box 50-2**).

Synonyms and Related Terms

Myeloid and lymphoid neoplasms with *PDGFRA* rearrangement; myeloid and lymphoid neoplasms associated with *PDGFRA* rearrangement; myeloid/lymphoid neoplasm with *PDGFRA* rearrangement.[4]

Epidemiology

There is a marked male predominance with a male-to-female ratio of approximately 17:1. The median age of presentation is in the late 40s. It is the most common rearrangement among M/LN-eo-TK cases.

Etiology

The cause of this disorder is unknown. Rare cases have been reported to occur after cytotoxic chemotherapy.

Clinical Features

There is a marked male predominance with splenomegaly, marked increase in serum vitamin B_{12}, and elevated serum tryptase.[29-31] Extramedullary lesions are very common, in around 40% of patients. End organ damage may occur from the release of enzymes and other proteins by the eosinophils, causing tissue destruction. Various organs may be affected, including the heart, lungs, skin, gastrointestinal tract, and nervous system. Because of bone marrow involvement and/or eosinophil deposition in other tissues, patients

may present with anemia or symptoms related to the particular organ involved, such as difficulty breathing/shortness of breath, cardiac failure, and pruritus. Peripheral blood eosinophilia is reported in >90% of patients.

Morphology

Peripheral blood: The majority of cases with *FIP1L1*::*PDGFRA* fusion present as a CMN with morphologic features resembling CEL, NOS (**Fig. 50-3**).[1-11,32] The peripheral blood smear typically demonstrates moderate to marked eosinophilia, although this is not invariable,[33] in the majority of cells exhibit mature cytology. There are typically very few or no eosinophilic myelocytes. The eosinophils may show cytologic abnormalities, including cytoplasmic hypogranulation or eccentric localization of granules, nuclear hyposegmentation, nuclear hypersegmentation, and/or cytoplasmic vacuolization. There is typically no monocytosis, circulating blasts, dysplastic platelets, or dysplastic granulocytes. The complete blood cell count may show anemia and/or thrombocytopenia in a subset of cases.

Bone marrow: The bone marrow is often hypercellular from eosinophilic hyperplasia with minimal dysplastic features in the erythroid and granulocytic lineages and no increase in blasts (**Fig. 50-3**). Megakaryocytes can be decreased, normal, or increased in number; morphologically, they may exhibit myeloproliferative neoplasm (MPN)-like features, dysplastic features, or be unremarkable. In addition, increased, interstitial, individually distributed, spindled mast cells (typically highlighted by immunohistochemical stains such as tryptase, CD117), which show

aberrant expression of CD25, are invariably present. These cases are negative for the *KIT* D816V mutation and usually do not show focal compact dense mast cell clusters as seen in systemic mastocytosis (SM), although this can rarely occur.[9,34] In cases that fulfill criteria for SM but are *KIT* negative, these patients should be tested for *PDGFRA*[9] and possibly other tyrosine kinase genes, depending on the case. This constellation of bone marrow findings is often associated with variable degrees of reticulin fibrosis. The majority of cases present as a chronic disease process, and myeloid blasts are not elevated. However, some cases may present in myeloid or lymphoid blast phase (**Fig. 50-4**). In the event that a population of B- or T-lymphoblasts are detected, thorough evaluation for extramedullary disease and/or concern for a more aggressive disease course is warranted.

Immunophenotype

Given that the majority of cases present as a CMN without an increase in morphologic blasts, an extensive immunophenotypic analysis is typically not necessary except to demonstrate the atypical, spindled mast cells. The mast cells can be revealed by positive staining with CD117 and tryptase and show aberrant expression of CD25. If there is an increase in blasts, flow cytometric immunophenotyping or immunohistochemistry should be used to characterize the blast phenotype.

Genetic/Molecular Findings

By far the most common fusion gene partner for *PDGFRA* in this disorder is *FIP1L1* (80%–85% of cases). It should be noted that this fusion gene is cytogenetically cryptic and therefore requires either

FISH or a molecular-based strategy for detection.[32] This fusion is the result of an interstitial deletion on 4q12 whereby the *CHIC2* gene (located in-between *PDGFRA* and *FIP1L1*) is deleted. Because of the *CHIC2* deletion, the FISH strategy used in many laboratories to assess for the presence of this abnormality is often referred to as "CHIC2 FISH or FISH for the *CHIC2* deletion" (**Fig. 50-5**). Alternative methods to FISH include RT-PCR based assays to specifically detect the fusion gene or RNA sequencing to detect the gene fusions.

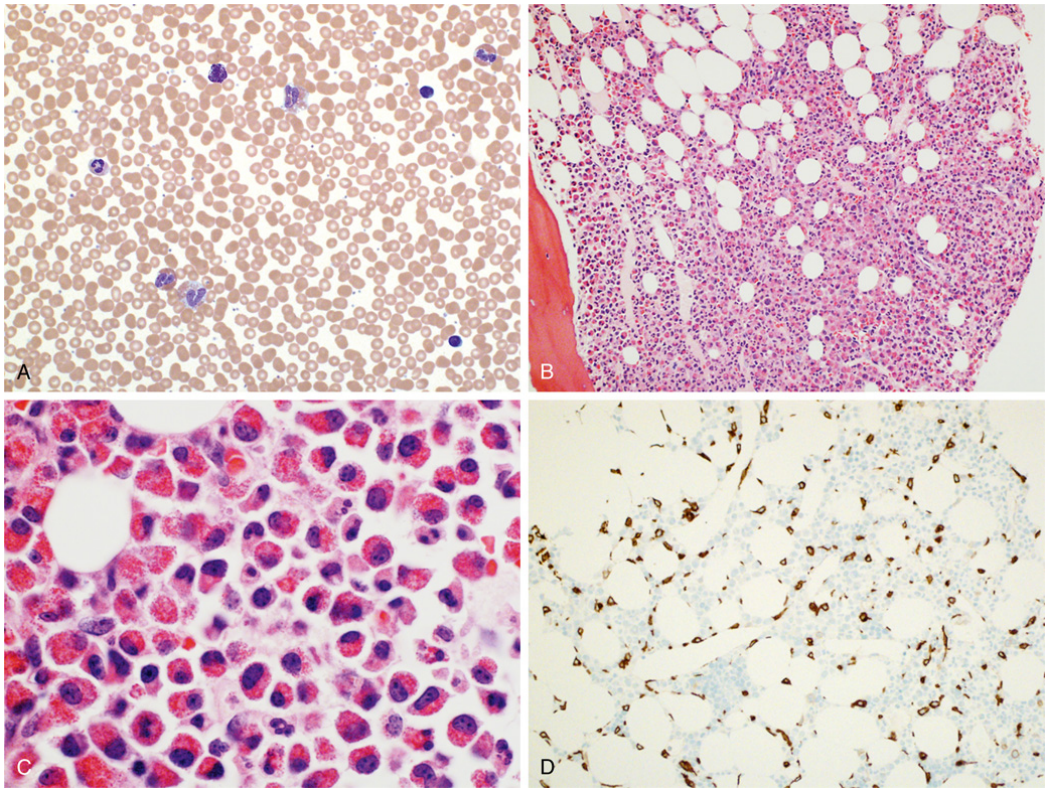

FIGURE 50-3 Myeloid neoplasm with eosinophilia and *FIP1L1*::*PDGFRA* rearrangement.A, A peripheral blood smear demonstrates hypereosinophilia (absolute eosinophil count of 2.3 × 10^9/L) without concomitant anemia or thrombocytopenia in a 59-year-old male patient who presented with weight loss. In this image, two of the four eosinophils display atypical cytologic features, including degranulation, vacuolization, and eccentric localization of granules in the cytoplasm. No features of dysplasia in the granulocytic series, circulating blasts, or monocytosis are present. (1000× magnification, Wright-Giemsa). **B,** The bone marrow core

biopsy is hypercellular for age (50%–60%) and shows a striking eosinophilic infiltrate. Increased blasts are not present, and mast cells are not obvious (400× magnification, H&E [hematoxylin and eosin]). **C,** High-power magnification of the bone marrow core biopsy reveals striking eosinophilia with numerous eosinophilic precursors. An increased blast population is not present, and there are no abnormal mast cell infiltrates visible by morphology (1000× magnification, H&E [hematoxylin and eosin]). **D,** Mast cells are increased and spindle-shaped (atypical) and demonstrate the typical interstitial, individually distributed infiltration pattern (immunohistochemistry for CD117). When tested, the mast cells show aberrant CD25 expression (not shown). On rare occasion, the mast cells may form focal, compact, dense aggregates mimicking systemic mastocytosis.

In the case of an alternative fusion partner (**Box 50-2**), conventional cytogenetic studies may reveal an apparently balanced translocation involving the 4q12 locus, which serves as the initial clue to a rearrangement of *PDGFRA,* especially in the presence of eosinophilia. Specific genetic testing for *PDGFRA* rearrangements is needed in such cases to confirm this genetic alteration.

NGS can detect various mutations in myeloid disorder–associated genes in myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRA*. These genes are non-specific, have been

reported in less than half of cases, and include *ASXL1, BCOR, DNMT3A, ETV6, SRSF2,* and *RUNX1* genes.[5,9]

Postulated Cell of Origin/Normal Counterpart

Pluripotent hematopoietic stem cell that can differentiate into either a myeloid or lymphoid progenitor.

Clinical Course

Patients with the typical CMN or CEL-like presentation and the *FIP1L1*::*PDGFRA* fusion respond remarkably well to imatinib, the first-generation TKI therapy. Imatinib is highly successful in the treatment of these patients with long-term hematologic and molecular responses.[6,7,28] In situations of presentation in acute blastic phase or disease progression from an initial chronic phase, imatinib may continue to be used; however, induction chemotherapy and/or allogenic hematopoietic stem cell transplant is typically needed to achieve long-term remission. Case reports of variant fusion partners have also reported treatment success with TKI. Several activating point mutations in *PDGFRA* have also been identified that appear to demonstrate a similar sensitivity to TKI treatment.

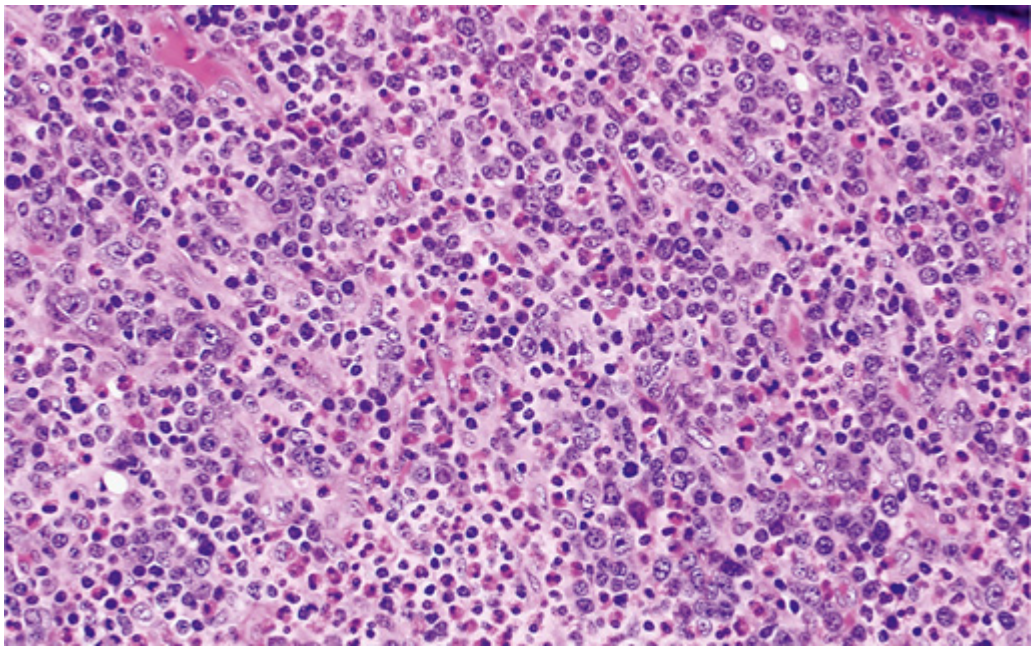

FIGURE 50-4 Myeloid sarcoma associated with eosinophilia and *FIP1L1*::*PDGFRA* rearrangement. This left axillary lymph node biopsy is from a 53-year-old male who presented with hypereosinophilia and lymphadenopathy. The lymph node biopsy showed features of a myeloid sarcoma and associated eosinophilia. The peripheral blood and bone marrow showed morphologic features of chronic eosinophilic leukemia. Genetic testing in both the bone marrow and lymph node demonstrated a "*CHIC2* deletion," indicating the presence of *FIP1L1*::*PDGFRA* rearrangement (1000× magnification, H&E [hematoxylin and eosin]).

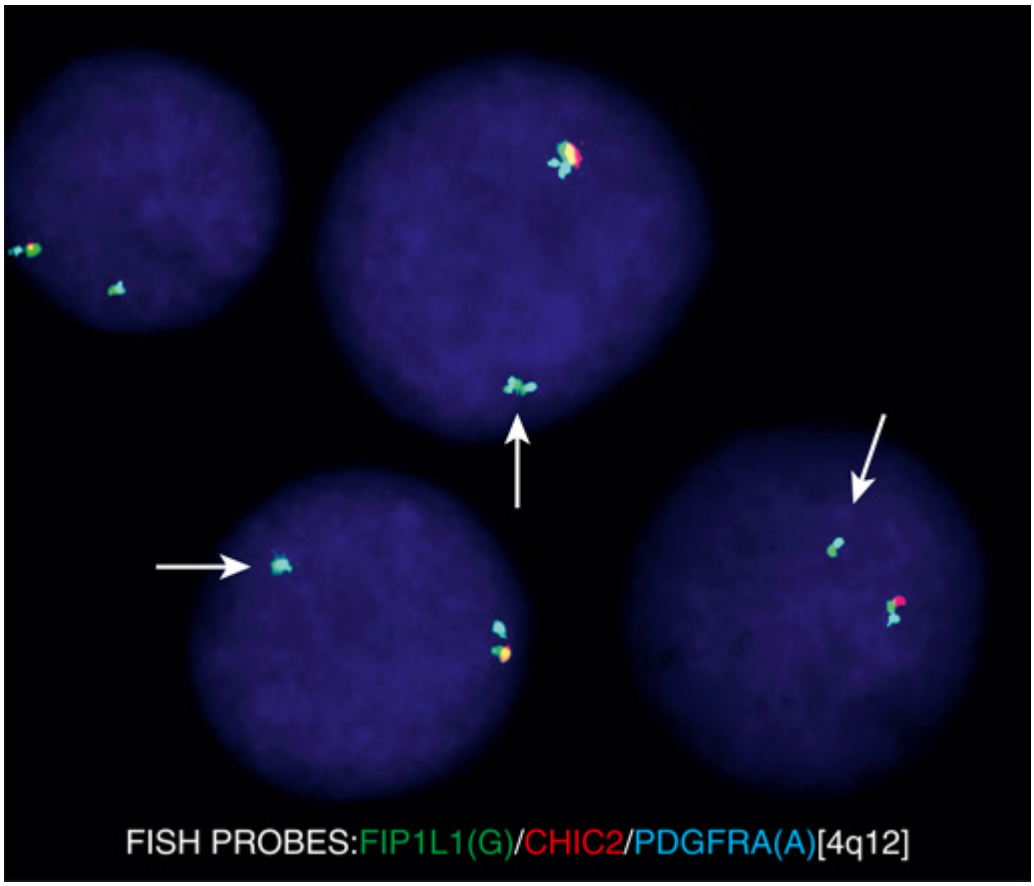

FIGURE 50-5 Interphase fluorescence in situ hybridization (FISH) demonstrating the *FIP1L1*::*PDGFRA* fusion via *CHIC2* deletion. On the long arm of chromosome 4 at locus 4q12, the *FIP1L1, CHIC2,* and *PDGFRA* genes reside in a row when moving telomeric. In this assay, the FISH probes are labeled *green* for *FIP1L1, red* for *CHIC2,* and *aqua* for *PDGFRA*. A normal signal pattern is seen as three probes colocalized together. In the situation of *FIP1L1*::*PDGFRA* fusion, the red signal *(CHIC2)* is deleted (absent), leaving behind just the green

and aqua signals (*arrows* show the abnormal signal).

Treatment resistance is unusual, but resistance to imatinib may be acquired over time in some patients as a result of a T6741 or D842V mutation.[35,36] In these situations, transitioning to a second- or third-generation TKI can be helpful.

Differential Diagnosis

The differential diagnosis is incredibly broad and includes both primary and secondary causes of eosinophilia. As such, following some type of methodical testing algorithm is suggested to arrive at the correct final diagnosis. If a reactive cause or underlying unrelated neoplastic process (e.g., carcinoma, T-cell lymphoma) is not present and/or does not explain the clinical and/or pathologic picture, additional immunophenotypic and genetic testing may be required for further evaluation. In particular, the age (younger) and sex (male) at presentation, along with the eosinophilia and atypical mast cell proliferation in the absence of other well-defined genetic abnormalities such as *BCR*::*ABL1*, inversion should draw attention to myeloid/lymphoid neoplasms with eosinophilia and *PDGFRA* rearrangement as a possible diagnosis.

In the occasional cases that do not exhibit peripheral blood eosinophilia, in which eosinophilia is minimal, or that present as an acute leukemia, several other clinicopathological features may help raise suspicion for this entity. These features include (1) bone marrow involved by a CMN that is difficult to put in a specific subtype and lack of disease-defining molecular genetic features in a young male patient; (2) increased eosinophils in tissue or bone

marrow biopsy despite no peripheral blood eosinophilia; (3) complex disease presentation with extramedullary involvement; (4) persistent myeloproliferative features after achieving remission of acute leukemia—eosinophilia may emerge; and (5) atypical mast cell proliferation with aberrant CD25 expression but *KIT* mutation testing is negative. With respect to the latter, the mast cell proliferation may be quite striking in rare cases, showing focal compact dense aggregate formation, spindled mast cell morphology, and aberrant CD25 expression mimicking SM. The disease biology, treatment implications, and response to treatment are vastly different between myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRA* and SM. It is therefore prudent to lower one's threshold for suspicion and discuss performing more in-depth testing (FISH or RNA sequencing) to evaluate for occult, potentially targetable, genetic rearrangements and/or point mutations.

Myeloid/lymphoid neoplasms with eosinophilia can exhibit other clinical presentations, including AML and, rarely, T-ALL or myeloid sarcoma (**Table 50-1**)[1-11,34,37-39] (**Fig. 50-4**). In some cases, the presentation is complex with an extramedullary blastic proliferation and CMN in the bone marrow. Alternatively, the extramedullary presentation may precede or succeed the detection of the CMN in the bone marrow. When there is significant eosinophilia in an extramedullary tissue site with a lymphoblastic lymphoma/myeloid sarcoma, molecular testing for a rearrangement of *PDGFRA* (and *PDGFRB, FGFR1, JAK2, FLT3,* and *ABL1*) should be considered.

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *PDGFRB*

Definition

A myeloid or lymphoid neoplasm that frequently but not invariably is associated with eosinophilia that has a demonstrable rearrangement of the *PDGFRB* gene.[1-5,9-11,40-43] In the rare case of de novo presentation as B-ALL or T-ALL, if the *PDGFRB* rearrangement is not present in background myeloid cells, the best diagnosis is Philadelphia-like B-ALL or de novo T-ALL with *PDGFRB* rearrangement.

Table 50-1

aCML, Atypical chronic myeloid leukemia; *AML,* acute myeloid leukemia; *B-ALL ,* B-acute lymphoblastic leukemia; *CEL, NOS,* chronic eosinophilic leukemia, not otherwise specified; *CMML,* chronic myelomonocytic leukemia; *MDS,* myelodysplastic syndrome; *MDS/MPN,* myelodysplastic/myeloproliferative neoplasm; *MPAL,* mixed phenotype acute leukemia; *MPN,* myeloproliferative neoplasm; *MPN, NOS,* myeloproliferative neoplasm, not otherwise specified; *MS,* myeloid sarcoma; *SM,* systemic mastocytosis; *T-ALL,* T-lymphoblastic leukemia.

* A complex presentation is defined as presentation as a chronic myeloid neoplasm in the peripheral blood and bone marrow and a lymphoblastic lymphoma/myeloid sarcoma/mixed phenotype acute leukemia in an extramedullary site.

† If the clinical presentation is typical B-lymphoblastic leukemia/lymphoma without an underlying or associated myeloid neoplasm with eosinophilia, the disease should be classified as Philadelphia-like/*BCR*::*ABL1*-like B-ALL.

Synonyms and Related Terms

Myeloid and lymphoid neoplasms with *PDGFRB* rearrangement; myeloid and lymphoid neoplasms associated with *PDGFRB* rearrangement; myeloid/lymphoid neoplasm with *PDGFRB* rearrangement; chronic myelomonocytic leukemia (CMML) with eosinophilia and t(5;12).

Epidemiology

This neoplasm shows a slight male predominance with a male-to-female ratio of 2:1. The age range of presentation is quite broad, from children to the elderly; however, like myeloid and lymphoid neoplasms with *PDGFRA* rearrangement, the median age is in the 4th decade of life.

Etiology

The cause of this disorder is unknown. Rare cases have been reported after cytotoxic chemotherapy.

Clinical Features

There is a slight male predominance, and splenomegaly is typical. Hepatomegaly may also be seen but is less common.[2,5,9] Serum tryptase may be elevated but is not typically markedly increased. End organ damage may occur as a result of the release of enzymes and other proteins by the eosinophils. Because of bone marrow involvement and/or eosinophil deposition in various tissues, patients may present with symptoms related to the particular organ involved such as difficulty breathing/shortness of breath (respiratory system), cardiac failure (heart), and pruritus (cutaneous involvement).

Morphology

Similar to the other tyrosine kinase gene rearrangements described in this chapter, myeloid/lymphoid neoplasms with eosinophilia and *PDGFRB* rearrangement show a heterogeneous presentation in the peripheral blood/bone marrow. This may include CMML with eosinophilia (**Fig. 50-6**), CEL (**Fig. 50-7**), atypical CML (aCML), a CMN that is difficult to categorize, AML, lymphoblastic leukemia, and SM (rare). In extramedullary tissue sites, transformation to or presentation as myeloid sarcoma or lymphoblastic leukemia/lymphoma may occur. If the presentation is typical B-ALL without an underlying (including preceding or succeeding) or associated myeloid neoplasm with eosinophilia, then the disease should be reclassified as Philadelphia-like/*BCR*::*ABL1*-like B-ALL according to the ICC.[2,3,5,9]

Peripheral blood: The peripheral blood often demonstrates leukocytosis, including eosinophilia (but not invariable) and associated monocytosis in those cases that resemble CMML (**Fig. 50-6**). Eosinophil morphology may show abnormal features, such as uneven granulation, cytoplasmic vacuolization, or abnormal nuclear segmentation or lobulation but is not always present. Monocytosis in combination with eosinophilia suggests the presence of and appropriate testing for a *PDGFRB* rearrangement. Only about three-quarters of cases are associated with eosinophilia; therefore, it is imperative that the reviewing pathologist and clinician consider this genetic abnormality, particularly when the karyotype may not be suggestive.

Bone marrow: The bone marrow is hypercellular with a variable admixture and increase in eosinophils (Figs. **50-6** and **50-7**),

granulocytes, monocytes, and mast cells. Like myeloid/lymphoid neoplasms with eosinophilia and *PDGFRA* rearrangement, the bone marrow, in addition to the features distinctive to the CMN disease presentation, may show increased, interstitial, individually distributed spindled mast cells (typically highlighted by immunohistochemical stains such as tryptase, CD117) that show aberrant expression of CD25. Rarely, focal compact dense clusters of mast cells may be seen mimicking SM. Megakaryocytes can be unremarkable or show dysplastic features; occasionally, there are myeloproliferative-type megakaryocytes.

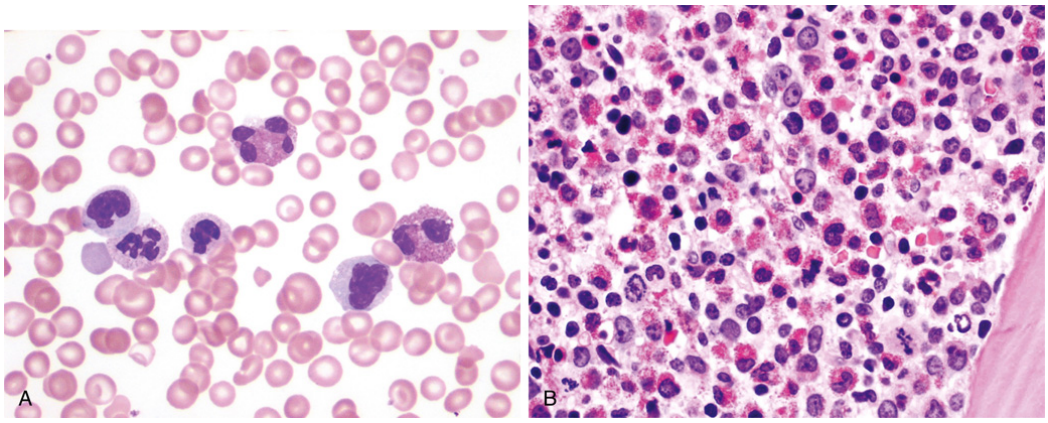

FIGURE 50-6 Peripheral blood film **(A)** and bone marrow biopsy **(B)** showing marked eosinophilia in a patient with monocytosis, resembling chronic myelomonocytic leukemia. Cytogenetic analysis revealed t(5;12)(q31;p12), *ETV6*::*PDGFRB*.

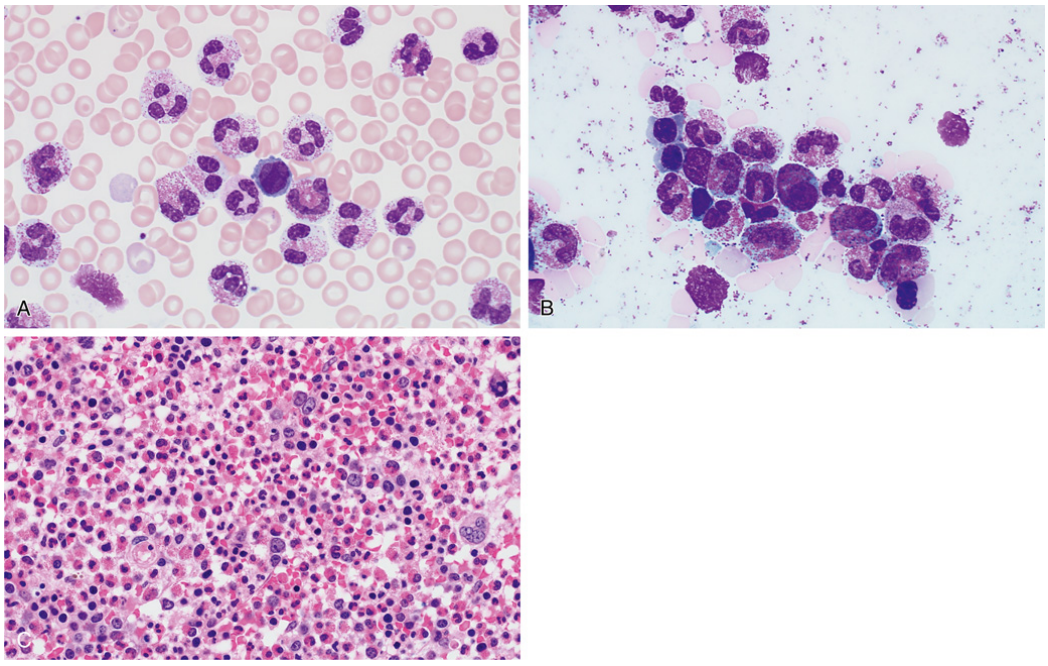

FIGURE 50-7 Myeloid neoplasm with eosinophilia and *ETV6*::*PDGFRB* rearrangement presenting with pathologic features resembling chronic eosinophilic leukemia.A, A peripheral blood smear from a 62-year-old male patient shows marked hypereosinophilia (absolute eosinophil count of 50.4×10^9/L) with concomitant anemia and marked thrombocytopenia. The majority of eosinophils demonstrate at least a subset of atypical cytologic features, including hypogranulation and vacuolization. No features of dysplasia in the granulocytic series, circulating blasts, or monocytosis are present (1000× magnification, Wright-Giemsa). **B,** The bone marrow aspirate smear confirms a striking increase in eosinophils and eosinophilic

myelocytes without a significant increase in myeloid blasts, monocytosis, or granulocytic/erythroid dysplastic features (1000× magnification, Wright-Giemsa). **C,** The bone marrow core biopsy is markedly hypercellular for age (100%) and is predominated by eosinophils and eosinophilic precursors with diminished quantities of erythroid precursors and megakaryocytes (600× magnification, H&E [hematoxylin and eosin]).

In the uncommon situations in which the disease presents as an acute leukemia or a combination of both a chronic myeloid process and an acute leukemia, increased blasts will be seen either in the bone marrow or in an extramedullary tissue site. Demonstration of the *PDGFRB* rearrangement in both the chronic and acute processes is necessary to exclude the possibility of an isolated acute lymphoblastic leukemia presenting as Philadelphia-like/*BCR*::*ABL1*-like B-ALL.

Immunophenotype

Given that the majority of these cases present as a CMN without an increase in morphologic blasts, an extensive immunophenotypic analysis is typically not necessary except to demonstrate the atypical, spindled mast cells and rule out eosinophilia with a T-cell neoplasm or lymphocyte variant hypereosinophilic syndrome. The mast cells can be revealed by positive staining with CD117 and tryptase and show aberrant expression of CD25. In the cases presenting as an

acute leukemia, increased blasts are present. Immunophenotyping in those instances is necessary to determine the acute leukemia lineage.

Genetics/Molecular Findings

The majority of cases carry t(5;12)(q32;p13.2) with formation of an *ETV6*::*PDGFRB* fusion. This is usually karyotypically evident; however, subsequent genetic testing via FISH or other methodology is mandatory to demonstrate a *PDGFRB* rearrangement. Rarely, the translocation may involve three or more chromosomes; therefore, recognition by the geneticist of the involvement of the genetic location on 5q31-q33 is important to prompt confirmatory FISH or other testing. This has both diagnostic and therapeutic implications given these entities are exquisitely sensitive to imatinib therapy.[6,7,28] Not all instances involving 5q31-5q33 show involvement of *PDGFRB,* which is significant in that the neoplasm would not fall into this diagnostic category and the treatment benefits from a TKI would not be present.

Though the most common partner with *PDGFRB* is *ETV6,* more than 30 alternate genes have been reported (**Box 50-2**). It is increasingly recognized that *PDGFRB* rearrangements may be cryptic both karyotypically or by FISH, especially in cases where *PDGFRB* is rearranged with other partner genes. Therefore, if there is suspicion of this abnormality at the molecular level and/or that it is involved in complex genetic rearrangements, multiple genetic testing modalities (FISH, RNA sequencing) are often needed to identify the rearrangements.[9,44,45]

PDGFRB rearrangements with alternative partners including, but not limited to, *EBF1, SSBP2, TNIP1, ZEB2,* and *ATF7IP* often present

as de novo B-ALL, which is currently classified as Philadelphia-like/*BCR*::*ABL1*-like B-ALL and not as a myeloid/lymphoid neoplasm with eosinophilia and *PDGFRB* rearrangement. Distinction between myeloid/lymphoid neoplasm with eosinophilia and *PDGFRB* rearrangement and *BCR*::*ABL1*-like B-ALL, similar to myeloid/lymphoid neoplasm with eosinophilia and *PDGFRA* rearrangement, is determined based on the presence or absence of an underlying myeloid neoplasm with rearrangement of *PDGFRB*.

NGS can detect various mutations in myeloid disorder-associated genes in myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRB*. These genes are non-specific, have been reported in less than 50% of cases, and include *ASXL1, TET2, BCOR, ETV6, STAG2,* and *RUNX1*.[5,9]

Postulated Cell of Origin/Normal Counterpart

Pluripotent hematopoietic stem cell that can differentiate into either a myeloid or lymphoid progenitor.

Clinical Course

Similar to CMNs with rearrangement of *PDGFRA,* those with *PDGFRB* rearrangement respond remarkably well to imatinib TKI therapy, with long-term hematologic and molecular responses. In situations of presentation in blast phase or disease progression from an initial chronic phase, imatinib may continue to be used; however, induction chemotherapy and/or allogenic hematopoietic stem cell transplant is typically needed for long-term remission.[6]

Differential Diagnosis

Depending on the degree of laboratory and morphologic abnormalities, the initial differential diagnosis for a chronic myeloid process may be broad and include both primary and secondary causes of eosinophilia and a clonal myeloid neoplasm that lacks significant eosinophilia. In particular, those cases with monocytosis and eosinophilia should raise the distinct possibility of t(5;12) involving *PDGFRB*. For the other possibilities, a combination of appropriate immunophenotypic and genetic testing may be needed to distinguish reactive from clonal disorders and to further evaluate for a specific recurring genetic abnormality that would result in a specific ICC diagnosis. In particular, the age (younger) and sex (male) at presentation, along with the eosinophilia and/or monocytosis and atypical mast cell proliferation, should draw attention to "myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *PDGFRB*" as a possible diagnosis.

Though CEL-like or CMML presentations tend to predominate, it is important to recognize that other clinical presentations may include B-ALL and, less commonly, AML, T-ALL, or myeloid sarcoma (**Table 50-1**).[1-11,34,37-39] In some cases, the presentation is complex, with an extramedullary blastic proliferation and CMN in the bone marrow. Alternatively, the extramedullary presentation may precede or succeed the detection of CMN in the bone marrow. When there is significant eosinophilia in an extramedullary tissue site with a lymphoblastic lymphoma/myeloid sarcoma, molecular testing for a rearrangement of *PDGFRB* (and of *PDGFRA, FGFR1, JAK2, FLT3,* and *ABL1*) should be considered. In these situations, both entities harbor the same genetic alteration.

In the cases with an uncharacteristic presentation such as lack of significant peripheral blood eosinophilia and karyotypically cryptic, the clinicopathological features that help raise a suspicion of the presence of tyrosine kinase (TK) fusion (listed under Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *PDGFRA*) are also applicable to cases of *PDGFRB* rearrangement. When approaching these cases, it is important to lower the threshold for eosinophilia (many cases have mild eosinophilia rather than hypereosinophilia) to also consider tissue and bone marrow eosinophilia in addition to peripheral blood eosinophilia, to assess mast cells, to be cautious making a generic diagnosis of a CMN lacking a characteristic genetic alteration in a young patient, and to pay attention to the background bone marrow and complete blood cell count features in patients presenting in blast phase.

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *FGFR1*

Definition

A hematopoietic neoplasm with rearrangement of *FGFR1* that typically shows eosinophilia and may manifest as a CMN or as an acute leukemia (T-cell, B-cell, myeloid, and mixed phenotype).[1-11] This entity is heterogenous in its presentation.

Synonyms and Related Terms

8p11 myeloproliferative syndrome, 8p11 stem cell syndrome, myeloid and lymphoid neoplasms with *FGFR1* abnormalities, stem cell leukemia/lymphoma syndrome.[1-3,46-57]

Epidemiology

There is a slight male predominance with a male-to-female ratio of approximately 1.5:1. The median age at presentation is in the 3rd and 4th decades of life with a wide age range (toddler to octogenarian).[1-3,9,10,52]

Etiology

The etiology is unknown.

Morphology

The disease is well-known for its heterogenous and complex presentations, including CEL, myelodysplastic/myeloproliferative neoplasm (MDN/MPN), AML, T-ALL, or (less often) B-ALL or mixed-phenotype acute leukemia. There is a frequent association with peripheral blood and/or bone marrow eosinophilia (70%–80%), and extramedullary disease presentation is typical (**Table 50-1**). In fact, acute and chronic disease manifestations may occur concurrently or manifest subsequently (**Fig. 50-8**). For example, in cases that present as CEL, there may be subsequent transformation to AML (including myeloid sarcoma), T-ALL, B-ALL, or mixed-phenotype acute leukemia. Alternatively, some cases may present as acute leukemia, but it is only after treatment that an underlying *FGFR1*-rearranged CMN is appreciated. T-ALL in the extramedullary site (often lymph node) often shows an immature myeloid component in the periphery or perivascular location.

Like cases with *PDGFRA* or *PDGFRB* rearrangement, scattered spindle mast cells with aberrant CD25 expression are frequent, but only rarely do cases satisfy the diagnostic criteria for SM.[58,59] In the

latter scenario, such cases should not be diagnosed as SM with an associated myeloid neoplasm unless it is a legitimate unique occurrence of *FGFR1* rearrangement in the non–mast cells and *KIT* D816V is mutated in the mast cells. Rather, the case should be classified as an *FGFR1*-rearranged myeloid/lymphoid neoplasms with eosinophilia.

The disease phenotype may differ with different partner genes. Cases with *BCR*::*FGFR1* fusion tend to have hematologic features resembling those of CML with eosinophilia rather than those of CEL.[54,55] An unusual feature of *FGFR1OP1*::*FGFR1* is that five of the reported cases had polycythemia.[56,57]

Immunophenotype

Depending on the morphologic findings, more or less immunophenotypic studies may be needed to clarify the diagnostic process. If the case presents as CMN, assessment for an aberrant mast cell population (e.g., CD117, tryptase, CD25) may be all that is needed. If there is a proliferation of immature-appearing cells/blasts, then a more extensive immunophenotypic analysis is required. In the latter case, flow cytometric immunophenotyping is preferred, particularly when a diagnosis of mixed phenotype acute leukemia is being considered.

Genetics/Molecular Findings

FGFR1 is a tyrosine kinase that plays an essential role in the regulation of cell proliferation, differentiation, and migration and is located on 8p11.23. At the time of this writing, there were at least 14 gene partners reported to fuse with *FGFR1* (**Box 50-2**). *FGFR1* fusion genes form chimeric proteins that constitutively activate the

FGFR1 tyrosine kinase and associated downstream signalling pathways. The most common partners include *ZMYM2*(13q12) and *CNTRL*(9q33).

FGFR1 rearrangements are not cytogenetically cryptic[2,9,60-68]; however, the reported bands may range from 8p11.2 to 8p21, likely attributable to banding quality, the relatively small size of band 8p11, and the quality of chromosomal morphology. Given this variability in band reporting and the fact that not all cases that involve this chromosomal location will involve the *FGFR1* gene, confirmation of *FGFR1* gene involvement is mandatory.[69] This can be done using a break-apart FISH probe for *FGFR1*. However, ideally, an RNA sequencing methodology would be deployed to identify all fusion products.

These disorders appear to be enriched for *RUNX1* mutations when evaluated by gene sequencing studies.[70] Mutations in *RUNX1* may increase proliferation of the clone with the *FGFR1* fusion and contribute to disease evolution and poor outcome.[46,70]

Postulated Cell of Origin/Normal Counterpart

Pluripotent hematopoietic stem cell.

Clinical Course

The clinical outcome in this disorder is variable, as might be expected, given the diversity of disease presentations. However, many cases follow an aggressive course, terminating in blast phase/blast transformation in less than 3 years.[6] *FGFR1*-rearranged neoplasms do not respond to first-generation TKI (imatinib) therapy. Prognosis is poor for acute leukemias and transformed cases, so aggressive chemotherapy and hematopoietic stem cell

transplantation are considered the best curative option. Clinical trials evaluating newer agents, including FGFR1 inhibitors (e.g., pemigatinib) and third generation TKIs such as ponatinib, may provide positive results.[71-73]

Differential Diagnosis

The differential diagnoses include other morphologically similar entities such as MPNs, MDS/MPNs, and acute leukemias/extramedullary disease involvement by acute leukemia. A proper, and often exhaustive, genetic and immunophenotypic workup is required to distinguish these various entities. In situations of a complex presentation, CMN in the peripheral blood/bone marrow, and extramedullary involvement by acute leukemia, *FGFR1* rearrangement testing is needed, regardless of the presence of eosinophilia.

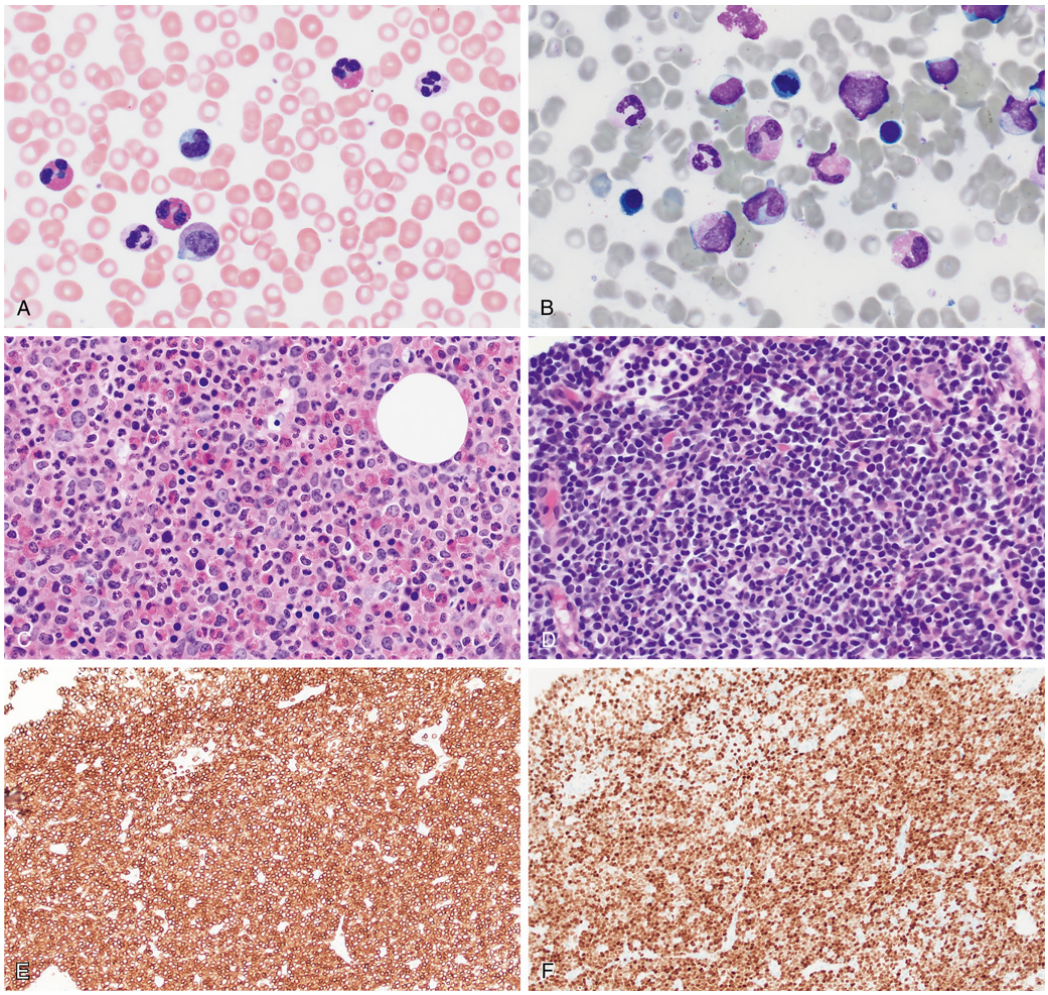

FIGURE 50-8 Myeloid/lymphoid neoplasm with eosinophilia and *FGFR1*-rearrangement presenting as chronic myelomonocytic leukemia with eosinophilia in the peripheral blood and bone marrow and concurrent T-lymphoblastic lymphoma in a left cervical lymph node.A, This peripheral blood smear from a 53-year-old male patient who presented with lymphadenopathy demonstrates hypereosinophilia (absolute eosinophil count 1.5

× 10^9/L) and borderline monocytosis (absolute monocyte count 1.1 × 10^9/L) (1000× magnification, Wright-Giemsa). **B,** A bone marrow aspirate smear demonstrates maturing trilineage hematopoiesis with an increase in eosinophils and precursors (approximately 40% of bone marrow elements). There was a slight increase in monocytes (12% of bone marrow elements). No significant dysplasia or increase in blasts is present (1000× magnification, Wright-Giemsa). **C,** The bone marrow core biopsy is packed and essentially effaced by an eosinophilic and myelomonocytic proliferation. Megakaryocytes and erythroid precursors were markedly decreased (600× magnification, H&E [hematoxylin and eosin]). **D,** Left cervical lymph node biopsy demonstrates diffuse effacement of nodal architecture by an intermediate size monotonous population of round to slightly indented cells with blastic chromatin consistent with an acute leukemic process. Extensive immunohistochemical stain demonstrated an immunophenotypic profile of T-lymphoblastic lymphoma (600× magnification, H&E [hematoxylin and eosin]). **E,** Left cervical lymph node biopsy demonstrates diffuse staining for cytoplasmic CD3 (immunohistochemistry for CD3). **F,** Left cervical lymph node biopsy

demonstrates diffuse staining for the immature marker TdT, confirming a diagnosis of T-lymphoblastic lymphoma (immunohistochemistry for TdT).

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *JAK2*

Myeloid/lymphoid neoplasms with eosinophilia and *PCM1*::*JAK2* and two genetic variants *ETV6*::*JAK2* and *BCR*::*JAK2*.

Definition

Myeloid and/or lymphoid neoplasms associated with a *JAK2* fusion.[1-5,9,74,75] The most common fusion partner for this entity is *PCM1*. Additional partner genes exist and are included in this diagnostic category, specifically, t(9;12)(p24.1;p13.2)/*ETV6*::*JAK2* and t(9;22)(p24.1;q11.2)/*BCR*::*JAK2*.

Synonyms and Related Terms

Myeloid or lymphoid neoplasm with *JAK2* rearrangement; myeloid/lymphoid neoplasms with *PCM1*::*JAK2* and genetic variants.

Epidemiology

Cases of myeloid/lymphoid neoplasms with eosinophilia and *PCM1*::*JAK2* fusion currently account for less than 70 total cases in the literature.[1-3,9,11,76-81] The median age at presentation is 50 years, with a wide age range, and there is a male predominance (>3:1 male-to-female ratio).

Etiology

The etiology is unknown.

Clinical Features

These neoplasms show a heterogenous presentation ranging from MPNs and MDS/MPN, most commonly (approximately 60%), to AML and B-ALL; extramedullary disease involvement is common (**Table 50-1**).[2,3,5,9,79-81] Organomegaly (hepatosplenomegaly) and/or lymphadenopathy are also very common. Rare presentations include manifestation of B-lymphoblastic crisis of an underlying CMN, myeloid sarcoma, pure erythroid leukemia or erythroblastic sarcoma, and T-cell lymphoma.[5,9,82] It has been reported that two cases of mycosis fungoides harbored the *PCM1*::*JAK2* fusion and that *JAK2* rearrangements may be seen in CD30-positive systemic T-cell lymphomas with anaplastic cytology.[83,84] Neither case exhibited eosinophilia. It remains debatable whether these cases belong to M/LN-eo-TK or T-cell lymphoma with *PCM1*::*JAK2*.

Morphology

Peripheral blood: Eosinophilia is common in patients with CMNs, ranging from mild to marked. Eosinophil morphology is variable, ranging from morphologically unremarkable forms to abnormal/dysplastic-appearing forms.

Bone marrow: The bone marrow shows the typical histopathologic "triad," which includes hypercellularity with an eosinophilic infiltrate, large aggregates of immature erythroid precursors (pronormoblasts), and myelofibrosis (**Fig. 50-9**).[2,5,9] The identification of these erythroid "microtumors" in the setting of

eosinophilia and MPN features should immediately prompt the pathologist to consider this diagnostic entity and initiate appropriate genetic testing. In some cases, erythroid hyperplasia, dysplasia in the erythroid, and granulocytic and/or megakaryocytic lineage may be seen.

Extramedullary sites: The features of an eosinophilic infiltrate, large aggregates of immature erythroid precursors (pronormoblasts), and myelofibrosis may be seen. If the pronormoblasts form large sheets and efface the extramedullary tissue architecture, this may indicate a diagnosis of erythroblastic sarcoma.[80,82]

Immunophenotype

Similar to other M/LN-eo-TKs, if blasts are not increased, immunophenotyping may serve as a tool to rule out other causes of eosinophilia and identify aberrant mast cells. Erythroid microtumors or extramedullary erythroid nodules can be confirmed by CD71 and E-cadherin. For cases with increased blasts, flow cytometry immunophenotyping and immunohistochemistry will help characterize blast phenotype.

Genetics/Molecular Findings

JAK2 is a cytoplasmic tyrosine kinase that plays an important role in hematopoiesis and cell proliferation. Constitutive activation of the JAK pathway by the gene mutation *JAK2* V617F is common in Philadelphia-negative MPNs (essential thrombocytosis, polycythemia vera, and primary myelofibrosis).

In contrast to the common *JAK2* V617F mutation, chromosomal translocations involving *JAK2* are rare and have been reported in various hematologic malignancies.

JAK2 is located at the terminal band of the short arm of chromosome 9. The vast majority of *PCM*::*JAK2* cases are not cryptic and demonstrate t(8;9)(p22;p24.1) if sufficient metaphases are obtained. However, a translocation involving *JAK2* has the potential to be cytogenetically cryptic, especially if the partner gene happens to also be located at the terminal end of a chromosome. For extramedullary lesions, when karyotyping is not available, a high index of suspicion for this genetic abnormality is needed in the appropriate morphologic context and complex presentation. FISH or RNA sequencing should be used in clinical practice. Though *PCM1* is the most common partner, several additional partners have been reported (*ETV6* and *BCR*) (**Box 50-2**). The potential therapeutic benefit of targeted therapy (JAK2 inhibitors) warrants accurate and timely diagnosis of this genetic abnormality.[6,7,76,77,85]

Postulated Cell of Origin/Normal Counterpart

Pluripotent hematopoietic stem cell that can give rise to a proliferation of myeloid, erythroid, or B-lymphoid or T-lymphoid lineage cells.

Clinical Course

The disease course appears to be highly variable, with chronic phase disease showing a longer overall survival and a 5-year survival of approximately 80%.[6,9,74,80] The prognosis is dismal for patients who present with increased blasts or progress to acute leukemia. Targeted therapy with JAK2 inhibitors such as ruxolitinib may offer potential benefit,[76,77] but the response may be limited.[76,77,80,85] The 2024 National Comprehensive Cancer Network (NCCN) guidelines for myeloid/lymphoid neoplasms with eosinophilia and *PCM1*::*JAK2*

fusion state that a clinical trial is the preferred treatment option for patients with chronic phase disease.[7] Allogeneic stem cell transplantation has the promise of disease cure.

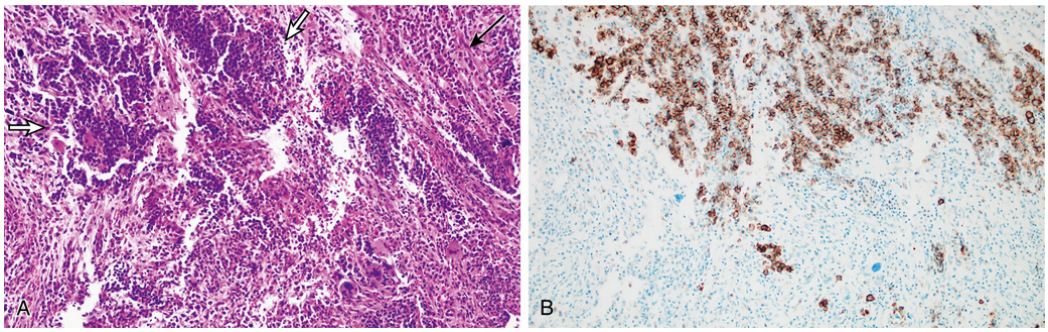

FIGURE 50-9 Myeloid/lymphoid neoplasm with eosinophilia and *PCM1*::*JAK2* fusion.A, The bone marrow core biopsy is markedly hypercellular for age (61-year-old patient) and demonstrates the typical "triad" histopathologic features, including clusters of early erythroid precursors/pronormoblasts *(block arrows)*, fibrosis *(lower left and center of image)*, and eosinophilia *(single line arrow)* (400× magnification; H&E [hematoxylin and eosin]). **B,** Clusters of early erythroid precursors/pronormoblasts are nicely highlighted by an immunohistochemical stain for E-cadherin.

Differential Diagnosis

The differential diagnostic considerations include the other morphologically similar entities such as MDS/MPN with eosinophilia, MPNs, CEL, NOS, and acute leukemias/extramedullary

disease involvement by acute leukemia. A proper, and often exhaustive, genetic and immunophenotypic workup is required to distinguish among these various entities. In situations of a complex presentation, CMN in the peripheral blood/bone marrow, and extramedullary involvement by acute leukemia, *JAK2* rearrangement testing is needed, regardless of the presence of eosinophilia.

JAK2 rearrangements are common in de novo Philadelphia-like B-ALL. Frequent partners including *SSBP2, PAX5, USP25,* and *ZNF274*. Patients with de novo B-ALL with *PCM1*::*JAK2* and no apparent myeloid component or eosinophilia may be best classified as Philadelphia-like B-ALL. Demonstration of a *JAK2* rearrangement in the myeloid cells in cases presenting as B-ALL and a prior history of a *JAK2*-rearranged CMN or *JAK2*-rearranged myeloid cells after treatment would support a diagnosis of myeloid/lymphoid neoplasm with *JAK2* rearrangement.

Variants of Myeloid/Lymphoid Neoplasms With Eosinophilia and *JAK2* Rearrangement (Not *PCM1*::*JAK2*)

BCR::JAK2: t(9;22) (p24;q11.2)

This is a rare myeloid/lymphoid neoplasm with fewer than 20 documented cases reported in the literature.[2,3,5,9,86-88] *BCR*::*JAK2* cases have a heterogeneous clinical presentation. These neoplasms have been predominantly classified as CML-like MPN, MPN with eosinophilia, and aCML; less often, they are classified as B-ALL, AML, and mixed phenotype acute leukemia. The presence of both myeloid and lymphoid neoplasms in patients with *BCR*::*JAK2* fusion suggests this genetic alteration occurs in a pluripotent progenitor stem cell. In the cases of B-ALL, the alternate diagnostic possibility

of Philadelphia-like B-ALL should be rendered if there is no evidence of a preceding, concurrent, or subsequent underlying CMN.

The median age at time of presentation is approximately 50 years, although there is a wide range from toddler to the seventh decade of life.[2,5,6,81,83,84] The histologic bone marrow features do not appear, thus far, to show the classic triad features of *PCM1*::*JAK2* (eosinophilic infiltrate, large aggregates of immature erythroid precursors [pronormoblasts], and myelofibrosis).[9] Myeloid neoplasms with eosinophilia and *BCR*::*JAK2*/t(9;22) (p24;q11.2) usually do not respond to *BCR-ABL1* TKIs, a therapy that is effective for CML.[85]

ETV6::JAK2: t(9;12)(p24;p13.2)

Less than 15 cases of this entity have been described to date. Of these, the majority present as acute lymphoblastic leukemia (mostly B lineage, but a few T lineage); a minor subset presents as a chronic neoplasm such as CEL, myelodysplasia, or aCML.[2,9,74,89,90] The histologic bone marrow features do not appear, thus far, to show the classic triad features of *PCM1*::*JAK2* (eosinophilic infiltrate, large aggregates of immature erythroid precursors [pronormoblasts], and myelofibrosis).[9] The cases with B-ALL presentation may belong more appropriately to the ICC category of Philadelphia-like B-ALL if there is no evidence of a preceding, concurrent, or subsequent underlying CMN.

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *FLT3*

Definition

Myeloid/lymphoid neoplasms that harbor an FMS-related receptor tyrosine kinase 3 *(FLT3)* rearrangement that results in the formation of a fusion gene involving *FLT3*.

Synonyms and Related Terms

Myeloid/lymphoid neoplasms with eosinophilia and *FLT3* rearrangement.[4]

Epidemiology

The disease appears to be slightly more common in men, with a male-to-female ratio of approximately 1.4:1.0. There is a broad range of age at presentation, with the median age in the 50s.

Etiology

The etiology is unknown.

Clinical Features

Like the other myeloid/lymphoid neoplasms associated with eosinophilia and a rearrangement of *PDGFRA, PDGFRB, FGFR1,* and *JAK2,* hematopoietic neoplasms with *FLT3* rearrangement share some clinical and morphologic overlap (**Table 50-2**).[3,5,9,91,92] Patients typically present with peripheral blood abnormalities, including leukocytosis, occasionally monocytosis, and cytopenias. Eosinophilia is common but not invariably present (or it can be mild). Lymphadenopathy, splenomegaly, and extramedullary mass lesions are common. Clinical features are a manifestation of the disease presentation(s) and may include fatigue, easy bruising, rash, itching, or effects of extramedullary disease involvement.

Morphology

The pathologic presentation is heterogenous, including as a CMN (CEL-like, CMML-like, aCML, myelodysplastic syndromes), a higher grade myeloid disorder with excess blasts, or an acute leukemia (T-ALL, B-ALL, and myeloid sarcoma) or as mixed lineage neoplasm (mixed phenotype acute leukemia) (**Fig. 50-10**). Extramedullary disease involvement is common and has been described in two-thirds of cases. Two cases of T-cell lymphoma have been reported.

Table 50-2

AML, Acute myeloid leukemia; *CEL,* chronic eosinophilic leukemia; *ETP,* early T-cell precursor ALL; *MDS,* myelodysplastic syndrome; *MDS/MPN,* myelodysplastic/myeloproliferative neoplasm; *MPAL,* mixed phenotype acute leukemia; *MPN-eo,* myeloproliferative neoplasm with eosinophilia; *MS,* myeloid sarcoma; *T-ALL,* T-lymphoblastic leukemia/lymphoma.

Peripheral blood/bone marrow: The peripheral blood and bone marrow features vary depending on the type of disease presentation. There is often, but not invariably, eosinophilia. There may be monocytosis in cases with a CMML-like appearance or dysgranulopoiesis in cases with aCML-like presentation. Features resembling SM may be seen, and careful evaluation to distinguish true SM from an associated myeloid neoplasm is critical. If there is a higher-grade myeloid neoplasm, increased myeloid blasts are noted. Variable numbers of lymphoblasts or mixed lineage blasts may be present if there is a concurrent acute leukemia involving an extramedullary site.

Extramedullary sites: Extramedullary disease involvement by T-ALL, mixed phenotype acute leukemia, and myeloid sarcoma is common. Increased eosinophils and/or mast cells may be seen in these lesions.

Immunophenotype

Depending on the morphologic findings, more or less immunophenotypic studies may be needed to clarify the diagnostic process. If the case presents as a CMN, additional testing may not be needed. If there is a proliferation of immature-appearing cells/blasts, then a more extensive immunophenotypic analysis is required. In the latter case, flow cytometric immunophenotyping is preferred, particularly when a diagnosis of mixed phenotype acute leukemia is being considered.

Genetics/Molecular Findings

The *FLT3* gene, located on chromosome 13q12, belongs to the receptor tyrosine kinase family. Unlike *FLT3* mutations (common in AML), *FLT3* rearrangements in hematolymphoid neoplasms are rare, with fewer than 30 cases reported in the published literature.[3,5,9,91,92] The most common partner gene is *ETV6,* located at 12p13.2, accounting for just under half of the reported cases. The fusion of *ETV6*::*FLT3* is typically not cryptic in conventional chromosomal analysis, and involvement of the *FLT3* gene should be considered in cases of a hematopoietic neoplasm in which 13q12 is rearranged. The presence of the *FLT3* fusion gene should be confirmed using FISH probes for *FLT3,* RT-PCR, or RNA-sequencing methods because not all cases with 13q12 rearrangements involve the *FLT3* gene. Cases that have a chromosomal rearrangement at 13q12

wherein *FLT3* is not rearranged are excluded from this diagnostic category.

Additional partners that have been reported include *ZMYM2*/13q12.11, *BCR*(22q11), *TRIP11*/14q32.12, *SPTBN1*/2p16.2, *GOLGB1*/3q13.33, *CCDC88C*/14q32.11-14q32.12, and *MYO18A*/17q11.2.[91-96] Given that some partners (known or unknown) may be cryptic at the chromosomal level, additional testing with FISH and/or RNA sequencing should be strongly considered when there is a complex disease presentation with both a CMN and an extramedullary acute component, regardless of whether eosinophilia is present.

There is limited information regarding additional genetic mutations detected by NGS. These mutations include variants in *ASXL1, PTPN11, RUNX1, SETBP1, SRSF2, STAT5B, TET2, TP53,* and *U2AF1* genes, present in around 50% of cases.[5,9] The prognostic effect of these mutations is not known.

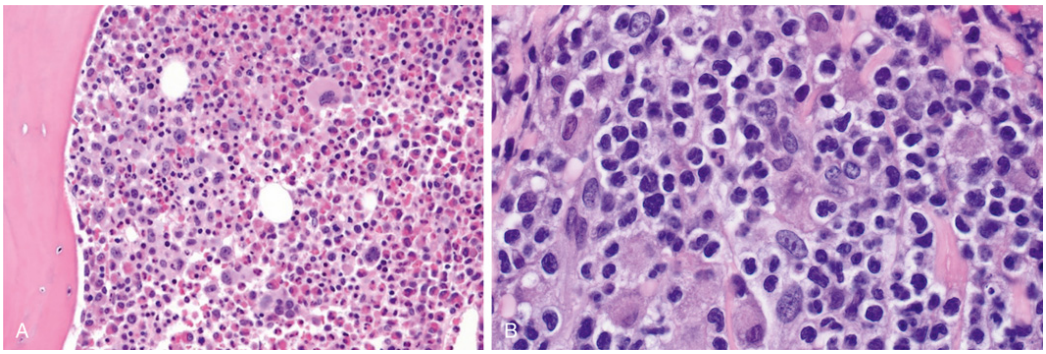

FIGURE 50-10 Myeloid/lymphoid neoplasm with eosinophilia and *FLT3*-rearrangement.A, The bone marrow core biopsy shows hypercellular bone marrow with numerous eosinophils, no overt megakaryocytic dysplasia, and no increase in blasts—very much the appearance of a chronic eosinophilic leukemia, not otherwise specified (1000× magnification; H&E [hematoxylin and eosin]). Cytogenetic studies confirmed by fluorescence in situ hybridization (FISH) indicated a *FLT3*-rearrangement. **B,** This lymph node biopsy from the same patient shows effacement by intermediate size cells with irregular nuclear contours, inconspicuous nucleoli, and somewhat immature-appearing chromatin. Eosinophils are notably absent. Extensive immunohistochemistry demonstrates that this is a T-lymphoblastic lymphoma. FISH identified a *FLT3*-rearrangement, indicating this acute leukemia is

genetically related to the chronic myeloid neoplasm with eosinophilia in the bone marrow.

Postulated Cell of Origin/Normal Counterpart

A pluripotent hematopoietic stem cell capable of myeloid and/or lymphoid differentiation.

Clinical Course

These cases tend be associated with an aggressive clinical course or early disease progression. A number of these cases have shown therapeutic benefit from FLT3 inhibitors such as sorafenib, sunitinib, or midostaurin monotherapy, although durability can be short, necessitating consideration of allogeneic hematopoietic stem cell transplantation for an attempt to cure.[7,92,97] Some patients may exhibit a durable clinical response to this therapy, whereas others may require more aggressive chemotherapy and/or allogeneic hematopoietic stem cell transplantation.[7]

Differential Diagnosis

The differential diagnoses include other morphologically similar entities such as aCML, CMML, CEL, NOS, and acute leukemias/extramedullary disease involvement by acute leukemia. The proper, and often exhaustive, genetic and immunophenotypic workup is required to distinguish among these various entities. In situations of a complex presentation as a CMN and as extramedullary involvement by acute leukemia, *FLT3* rearrangement testing is needed, regardless of eosinophilia presence.

Myeloid Neoplasms With Eosinophilia and *ETV6*::*ABL1*

Definition

This is a hematopoietic stem cell neoplasm of myeloid and/or lymphoid lineage associated with fusion of the *ETV6* and *ABL1* genes.

Epidemiology

There appears to be a slight male predominance, with a male-to-female ratio of 2:1. The median age of presentation is in the 5th decade of life.[3,5]

Etiology

The etiology is unknown.

Clinical Features

Most patients exhibit splenomegaly. The diagnosis is typically made in chronic phase and should be separated from de novo B-ALL with *ETV6*::*ABL1,* which may be diagnosed as Philadelphia-like/B-ALL.

Morphology

In a review of the literature, it was reported that patients with rearrangement of *ETV6*::*ABL1* present with a clonal myeloid proliferation and eosinophilia most often in chronic phase[98] (**Fig. 50-11**). However, like the other myeloid neoplasms with eosinophilia and recurring genetic rearrangements, AML may be seen at presentation, or the chronic cases may transform to AML, T-ALL, or B-ALL (**Table 50-2**). Patients often present with leukocytosis and anemia; basophilia also may be seen (**Fig. 50-11A**). There may be

thrombocytosis or thrombocytopenia. Eosinophilia is very common in myeloid neoplasm presentation. When presenting in chronic phase, the pathologic appearance may resemble CML, aCML, or MPN. However, the genetic rearrangement of *ABL1* should drive the classification. A subset of cases may exhibit extramedullary disease involvement.

Immunophenotype

Depending on the morphologic findings, immunophenotypic studies may be needed to clarify the diagnostic process. If the case presents as a CMN, minimal phenotyping may be needed. If there is a proliferation of immature-appearing cells/blasts, then a more extensive immunophenotypic analysis is required. In the latter case, flow cytometric immunophenotyping is preferred, particularly when a diagnosis of mixed phenotype acute leukemia is being considered.

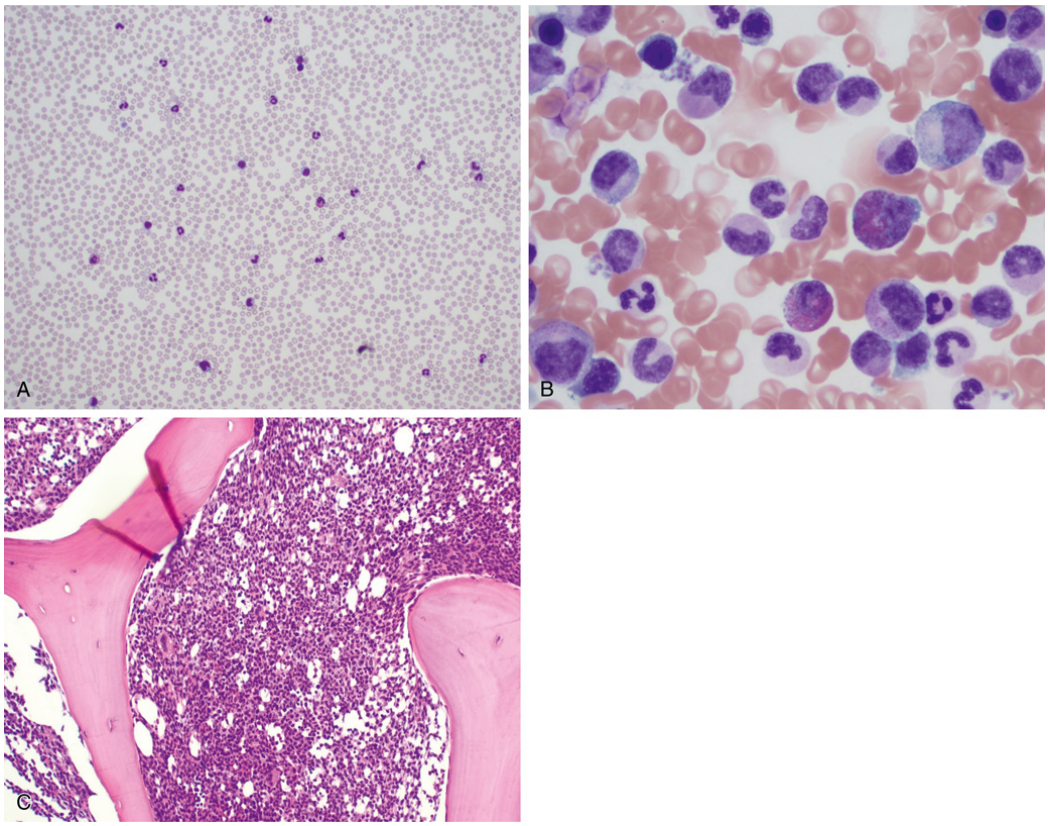

FIGURE 50-11 Myeloid neoplasm with *ETV6*::*ABL1*.A, Peripheral blood smear shows marked leukocytosis with eosinophilia, neutrophilia, occasional basophils, and monocytosis (400× magnification, Wright-Giemsa). **B,** Bone marrow aspirate smear reveals increased granulocytes with progressive maturation and unremarkable morphology, increased eosinophils, and relatively decreased erythrocytes (1000× magnification, Wright-Giemsa). **C,** Bone marrow core biopsy reveals hypercellular bone marrow with granulocytic hyperplasia; megakaryocytes are decreased in

number with unremarkable changes (600× magnification, H&E [hematoxylin and eosin]).

Genetics/Molecular Findings

The *ABL1* gene, located on chromosome 9q34.12, is a nonreceptor tyrosine kinase. *ABL1* rearrangements (excluding *BCR*::*ABL1*) in hematolymphoid neoplasms are rare.[3,5,9,11,98-102] The most common partner gene is *ETV6,* located at 12p13.2. Other partner genes are mostly identified in de novo T-ALL or Philadelphia-like B-ALL.

Postulated Cell of Origin/Normal Counterpart

Pluripotent hematopoietic stem cell

Clinical Course

Most patients present in chronic phase; however, disease progression to blast phase or extramedullary blastic tumor may occur in 30% of cases. Patients in chronic phase show various responses to TKIs.[103]

Differential Diagnosis

Given the known response to TKI treatment, it is absolutely critical to identify the *ETV6*::*ABL1* fusion or a variant-*ABL1* fusion and incorporate TKI treatment at an early stage of disease.[7,101] A high index of suspicion is critical to initiate proper testing in patients presenting with signs of myeloproliferative disease and eosinophilia. The differential diagnostic considerations include other morphologically similar entities such as CML, CMML, and CEL,

NOS. The proper genetic workup is required to distinguish among these various entities. Cases that present as B-ALL should be diagnosed as Philadelphia-like B-ALL in the absence of an underlying CMN.

CEL, NOS, IHE/IHES, and other Rare Reported Genetic Alterations Associated with Clonal Eosinophilia

Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL, NOS)

Definition

CEL, NOS is an MPN in which a clonal proliferation of eosinophils and precursors results in persistent eosinophilia involving the peripheral blood, bone marrow, and other tissues, with the eosinophilia being the dominant pathologic manifestation (**Box 50-3**). The diagnostic criteria for an alternative ICC-recognized hematopoietic neoplasm are not met. A diagnosis of CEL, NOS supersedes a diagnosis of aCML, MDS/MPN, NOS, or MPN-unclassified, but not classic MPN with MPN driver mutations or CMML with eosinophilia.

Box 50-3 Diagnostic Criteria for Chronic Eosinophilic Leukemia, Not Otherwise Specified (CEL, NOS)

AML, Acute myeloid leukemia; *MPN,* myeloproliferative neoplasm.

Peripheral blood hypereosinophilia (eosinophil count ≥1.5 × 10^9/L and eosinophils ≥10% of white blood cells)

Blasts constitute <20% of the cells in peripheral blood and bone marrow, not meeting any other diagnostic criteria for AML*

No tyrosine kinase gene fusion, including *BCR*::*ABL1* and other *ABL1, PDGFRA, PDGFRB, FGFR1, JAK2,* and *FLT3* fusions

Not meeting criteria for other well-defined MPNs, chronic myelomonocytic leukemia, or systemic mastocytosis†

Bone marrow shows increased cellularity with dysplastic megakaryocytes with or without dysplastic features in other lineages and often significant fibrosis, associated with an eosinophilic infiltrate, **OR** there are increased blasts ≥5% in the bone marrow and/or ≥2% in the peripheral blood

Demonstration of a clonal cytogenetic abnormality and/or somatic mutation(s)‡

---

* AML with recurrent genetic abnormalities and <20% blasts is excluded.

‡ In the absence of a clonal cytogenetic abnormality and/or somatic mutation(s) or increased blasts, bone marrow findings supportive of the diagnosis will suffice in the presence of persistent eosinophilia, provided other causes of eosinophilia having been excluded.

† CEL, NOS may occur as the associated myeloid neoplasm in cases of systemic mastocytosis with an associated myeloid neoplasm.

Synonyms and Related Terms

Chronic eosinophilic leukemia.[4]

Epidemiology

Given the longstanding challenges in definitively distinguishing many cases of true CEL, NOS from iHE/iHES, the true incidence of CEL, NOS (rare) is unknown. The range of age at presentation is quite broad (14–92 years) but on average is in the 60s.[104-106] There appears to be a male predominance with a male-to-female ratio of 2 to 3:1.[3,4,106] In one study, CEL, NOS represented 1.2% of patients with peripheral blood eosinophilia.[106]

Etiology

There are no known risk factors or a genetic predisposition to CEL, NOS.

Clinical Features

Though patients may occasionally present without symptoms, many patients appear to present with systemic symptoms. Like patients with other CMNs, those with CEL, NOS present with frequent constitutional symptoms (approximately 50%) such as fatigue, night sweats, fever, weight loss, abnormal complete blood count (including eosinophilia, cytopenia[s], and/or cytosis) in 70% to 80%, organomegaly (around 20%–30%) and elevated lactate dehydrogenase (approximately 60%). Unlike iHES, organ damage/dysfunction attributed to an eosinophilic infiltrate is not required for diagnosis but may be seen in 50% of patients. The symptoms directly attributable to hypereosinophilia may vary depending on the tissue site(s) involved. The most common sign is

skin rash (approximately 30%), but it may involve the gastrointestinal tract and cardiac, pulmonary, and central nervous systems. Depending on the degree of eosinophilic infiltration/end organ damage, endomyocardial fibrosis, scarring of cardiac valves with subsequent cardiac failure, and central nervous system dysfunction may result in serious morbidity and mortality. Thrombotic events are reported in approximately 10% of patients. In contrast to iHES, symptoms of allergy/hypersensitivity and upper respiratory symptoms such as asthma/cough are uncommon.

Morphology

Peripheral blood: The peripheral blood smear, by diagnostic criteria, shows hypereosinophilia (eosinophils ≥1.5 × 10^9/L and eosinophils ≥10% of white blood cells) that is often quite striking[3,5] (**Fig. 50-12**). There is usually accompanying leukocytosis, but this is not a requirement for the diagnosis. Eosinophils are mostly mature and may show a range of abnormal morphologic features, including abnormal granulation (hypogranulation or uneven granulation), cytoplasmic vacuoles, or abnormal nuclear lobation (**Fig. 50-12**). Of note, cytologic abnormalities of eosinophils are not specific to CEL, NOS or other neoplastic conditions and can also be seen in reactive conditions, but usually at a mild degree. Though cases of CEL, NOS may show normal eosinophil cytology, the absence of eosinophil cytologic abnormalities generally is more common in a reactive condition.[104] Anemia is present in the majority of patients, and thrombocytopenia may be seen.[104,105] Occasional cases show thrombocytosis. Mild basophilia has also been reported.[1] Some cases

exhibit mild monocytosis but do not meet diagnostic criteria for CMML. The peripheral blood blast percentage is typically low.[106]

Bone marrow: Bone marrow aspirate smears and core biopsy sections are generally significantly hypercellular, predominantly from an increase in eosinophils and granulocytic precursors with a resultant increase in the myeloid-to-erythroid ratio (>10) (**Fig. 50-12**).[26] Eosinophils may display cytologic abnormalities like those described in the peripheral blood, but they are often less striking. Megakaryocytes are essentially always abnormal, exhibiting most commonly myelodysplastic-type forms (hypolobated or small forms with distinctly separate nuclear lobes) (**Fig. 50-12**). In some cases, there may be a spectrum of megakaryocytic morphology including MDS-like forms and larger, hyperlobulated forms mimicking an MPN. Not infrequently, the proportion of increased eosinophils and granulocytes may render evaluation of megakaryocyte morphology more challenging. Regardless, careful morphologic assessment for abnormal megakaryocytes and/or the use of a megakaryocyte-associated immunohistochemical stain (e.g., CD61) may be helpful in discerning the presence of dysplastic megakaryocytes. Dysgranulopoiesis and dyserythropoiesis may be present and helpful in further supporting a diagnosis of CEL, NOS; however, this is not an invariable finding. Monocytes are not increased. Bone marrow blasts tend to represent, in most cases, less than 5% of the total nucleated cells. Increased reticulin fibrosis (grade 2 and grade 3 of 3) may be observed in approximately 20% to 30% of cases.

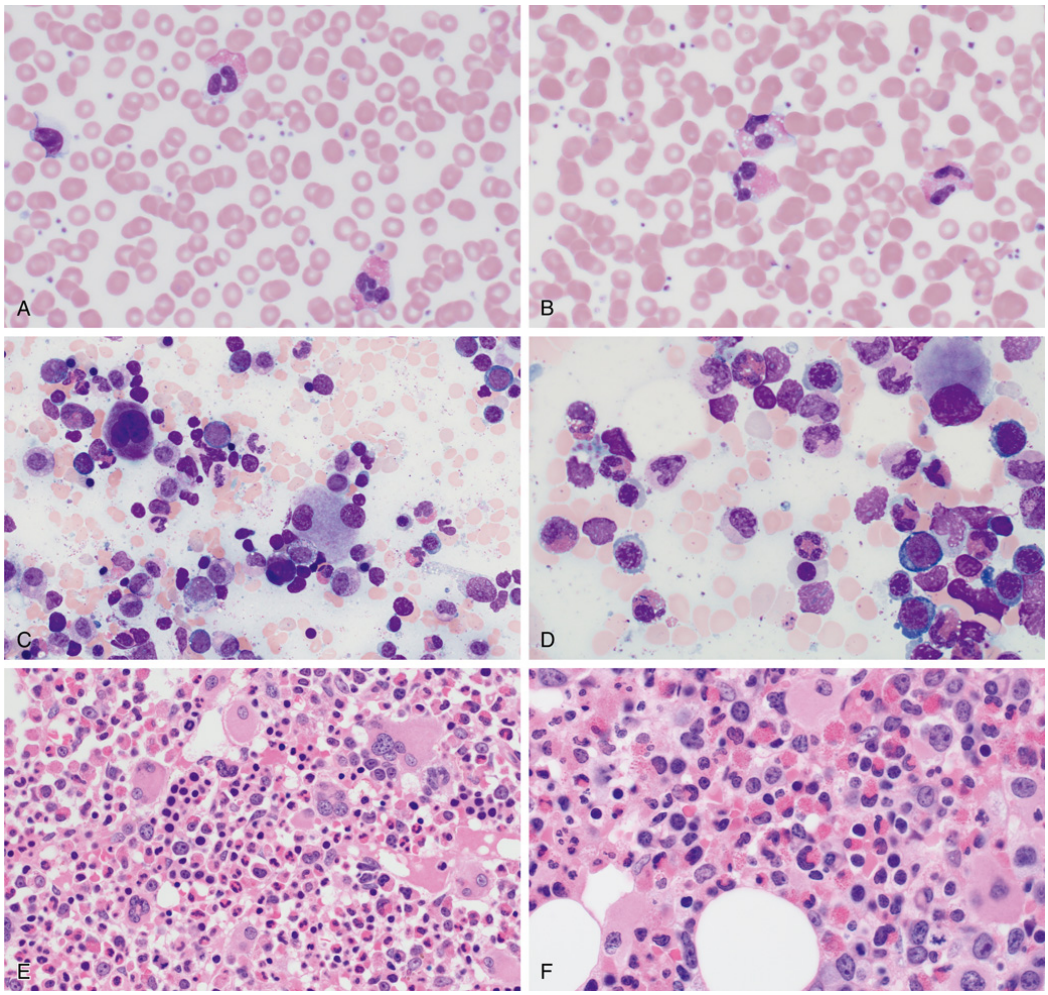

FIGURE 50-12 Chronic eosinophilic leukemia, not otherwise specified.A, The peripheral blood may show abnormal eosinophils characterized by hypolobated and hypogranular forms (1000× magnification, Wright-Giemsa). **B,** The peripheral blood may show abnormal eosinophils with vacuolization (1000× magnification, Wright-Giemsa). **C,** Bone marrow aspirate smears are spicular and hypercellular with very typical dysplastic-appearing megakaryocytes. In some instances, there may be

more of a spectrum of megakaryocyte morphology, including admixed larger (myeloproliferative neoplasm-like) forms. Dysgranulopoiesis and dyserythropoiesis are relatively uncommon. An increase in blasts is uncommon (1000× magnification, Wright-Giemsa). **D,** Bone marrow aspirate smears show a remarkable increase in eosinophils and dysplastic megakaryocytes (1000× magnification, Wright-Giemsa). **E,** The bone marrow core biopsy is essentially always hypercellular with increased eosinophils, resulting in a markedly increased myeloid-to-erythroid ratio. Admixed dysplastic-appearing megakaryocytes may be identified (600× magnification, H&E [hematoxylin and eosin]). **F,** The bone marrow core biopsy shows increased granulocytes and eosinophils with background dysplastic megakaryocytes. There is no overt increase in blasts (1000× magnification, H&E [hematoxylin and eosin]).

Immunophenotype/Genetic Testing

There are no specific immunophenotypic abnormalities in CEL, NOS. Given that CEL, NOS is largely a diagnosis of exclusion, other diagnoses that may exhibit a significant proportion of eosinophils must be excluded (**Fig. 50-2**). Immunohistochemical studies for CD117, tryptase, and CD25 will help exclude the presence of SM.

Caution should be exercised in the latter scenario, particularly if the bone marrow is markedly hypercellular with extensive eosinophilic infiltration, because SM may rarely be associated with CEL, NOS, meeting ICC criteria for SM with associated myeloid neoplasm (SM-AMN). Additional testing via immunohistochemistry and/or flow cytometry to exclude the presence of the lymphocytic variant of hypereosinophilic syndrome and T-cell/B-cell lymphoma is also suggested. The CD34-positive myeloblasts often exhibit immunophenotypic aberrancy if the flow cytometry tests used are designed for myelodysplastic syndromes or AML minimal residual disease detection, supporting a myeloid neoplasm.

Genetics/Molecular Findings

There is no specific cytogenetic or molecular genetic abnormality identified in CEL, NOS. However, the finding of a cytogenetic abnormality that is typically associated with myeloid neoplasms (trisomy 8, monosomy 7, etc.) may be useful in supporting the presence of a myeloid neoplasm best characterized as CEL, NOS.

With the increased availability of NGS panels, novel additional mutations are being identified in cases previously diagnosed as iHE/iHES.[104,107,108] In particular, in the setting of abnormal bone marrow morphology, gene mutations may help solidify a diagnosis of CEL, NOS rather than iHE/iHES. In one study, 11/98 patients with hypereosinophilic syndrome demonstrated a single positive mutation in *TET2, ASXL1, KIT, TP53, IDH2, JAK2,* and *SF3B1*.[107] In another study, 14/51 patients with the diagnosis of hypereosinophilic syndrome showed a single mutated gene in 7 patients and two or more mutated genes in another 7 patients.[104] In this series, the most

commonly mutated genes were *ASXL1, TET2, EZH2, SETBP1, CBL,* and *NOTCH*. *STAT5B* N642H has been reported in a small subset of patients referred with eosinophilia (1.6%), including patients who would be otherwise diagnosed with iHES.[109] Additional mutations that have been identified in other rare cases of clonal eosinophilia include those in *JAK2* exon 13 Leu583-Ala586DelInsSer,[110] *JAK1* R629_S632delinsSA in a patient with CEL,[111] and *CCT6B*.[112]

It is important to emphasize that, when only a single gene is mutated and the involved gene has been associated with clonal hematopoiesis of indeterminate potential (CHIP) and is at relatively low variant allele frequency (e.g. *ASXL1, TET2, JAK2*), it is incumbent upon the multidisciplinary team to discriminate true clonal eosinophilia from CHIP. It is also acknowledged that, like other myeloid neoplasms, occasional cases may not show a molecular genetic alteration with the currently available testing methods. In the presence of persistent hypereosinophilia and the other clinical features mentioned, abnormal bone marrow morphology consistent with a CMN should suffice to make a diagnosis of CEL, NOS.

Genetic testing should include assessment for *KIT* D816V, conventional cytogenetics to exclude a recurring genetic abnormality diagnostic of another entity such AML with inv(16) or CML, and exclusion of M/LN-eo-TK by appropriate cytogenetic, FISH, RT-PCR, and/or RNA sequencing technologies. In the authors' opinion, it is crucial to perform DNA and RNA extract and hold on to the bone marrow specimen to ensure there is material for NGS or RNA testing that may be necessary to evaluate for additional clonal abnormalities.

Clinical Course

Prognosis in patients with CEL, NOS is largely unfavorable, with median overall survivals reported in the literature of 14.4 months,[104] 16 months (range, 1–49 months),[106] and 22.2 months.[105]

Differential Diagnosis

CEL, NOS is a diagnosis of exclusion, and appropriate morphologic, clinical, laboratory, and genetic testing is necessary to exclude potential differential diagnoses such as iHE/iHES, the lymphocytic variant of hypereosinophilic syndrome, reactive hypereosinophilia (including T-cell/B-cell lymphoma and Hodgkin lymphoma), clonal hypereosinophilia associated with a well-defined hematopoietic neoplasm such as AML with inv(16) or CML, and M/LN-eo-TK.

In particular, with iHES, features that would tend to support the diagnosis of CEL, NOS include older age, higher white blood cell counts and AECs, cytopenia(s) and/or cytosis, frequent constitutional symptoms, hepatosplenomegaly, and high lactate dehydrogenase.[5,13,26,104] In contrast, patients with iHES are significantly younger, with more allergic or rheumatoid symptoms, skin rash, and pulmonary, gastrointestinal, an/or endocrine involvement. Genetic testing may also be helpful, particularly if a convincing myeloid neoplasm–associated cytogenetic abnormality is observed or if multiple myeloid disorder gene mutations are detected by NGS at high variant allele frequencies.

Idiopathic Hypereosinophilia/Hypereosinophilic Syndrome (iHE/iHES)

Definition

iHES is defined as persistent hypereosinophilia (≥6 months) with associated tissue/organ damage/injury from eosinophil-released cytokines or enzymes when the underlying cause, either a reactive or a clonal myeloid process, cannot be identified (**Box 50-4**). iHE or hypereosinophilia of unknown significance (HEus) is referred to as persistent hypereosinophilia of unknown etiology without related organ/tissue damage.

A diagnosis of iHE/HEus or iHES requires exclusion of all possible reactive causes and clonal neoplasms (**Box 50-2**).[6] With the improved recognition of eosinophilia cases that harbor a disease-associated molecular genetic abnormality, if appropriate and proper genetic workup is performed, the number of "idiopathic" cases should be significantly reduced.

Synonyms and Related Terms

Hypereosinophilic syndrome.

Epidemiology

The epidemiology is unknown given the overlap with CEL, NOS and difficulty distinguishing M/LN-eo-TK.

Box 50-4 Diagnosis of Idiopathic Hypereosinophilia or Idiopathic Hypereosinophilic Syndrome

Persistent peripheral blood hypereosinophilia (eosinophil count ≥1.5 × 10^9/L and ≥10% eosinophils)*

Organ damage and/or dysfunction attributable to tissue eosinophilic infiltrate[†]

No evidence of a reactive, well-defined autoimmune disease or neoplastic condition/disorder underlying the hypereosinophilia

Lymphocytic variant of hypereosinophilic syndrome ruled out[‡]

Bone marrow morphologically within normal limits except for increased eosinophils

No molecular genetic clonal abnormality, with the caveat of clonal hematopoiesis of indeterminate potential (CHIP)

---

[*] Preferably a minimal duration of 6 months if documentation is available.

[‡] The abnormal T-cell population needs to be detected immunophenotypically with or without T-cell receptor clonality by polymerase chain reaction.

[†] Hypereosinophilia of uncertain significance/idiopathic hypereosinophilia has no tissue damage; otherwise, should follow the same diagnostic criteria.

Etiology

There are no known risk factors or a genetic predisposition to iHE/iHES.

Clinical Features

The average age at presentation is in the high 40s but shows a broad spectrum (range 13.5–90 years). The male-to-female ratio is

approximately 1:1. In the study by Wang et al., when comparing hypereosinophilic conditions in morphologically abnormal bone marrow (presumably CEL, NOS) with the conditions in morphologically unremarkable bone marrow (presumably iHE/iHES), iHE/iHES showed fewer constitutional symptoms (approximately 20%), organomegaly (approximately 10%), elevated lactate dehydrogenase (approximately 25%), and thrombotic events (2%) and a greater proportion of allergies/hypersensitivity symptoms (approximately 30%), muscular/fasciitis (approximately 30%), gastrointestinal involvement (approximately 30%), and pulmonary symptoms (approximately 25%).[26] Compared with CEL, NOS, patients with iHE/iHES present with fewer cases of thrombocytopenia (10% vs. 33%), significantly lower AEC (3.9 vs. 11.2), similar degrees of anemia (13.1 vs. 12.2), and an overall normal average white blood cell count (11.5 vs. 29.7). Another study from a single institution demonstrated similar findings when clonal hypereosinophilic cases were excluded from the analysis.[107]

Morphology

Peripheral blood: The most striking peripheral blood feature in iHE/iHES is the hypereosinophilia (**Fig. 50-13**). Though some cases may exhibit eosinophilic cytologic abnormalities, the majority of these cases will show minimal alterations in eosinophils and are more noticeable in true CEL, NOS. Some cases may present with mild thrombocytopenia and/or anemia, but features suggestive of a myeloid disorder such as dysplasia, circulating blasts, monocytosis, and basophilia should not be observed.

Bone marrow: The bone marrow is normocellular or slightly hypercellular largely because of the eosinophilic infiltrate (**Fig. 50-13**). Aside from the eosinophils, the bone marrow should otherwise be morphologically unremarkable. Granulopoiesis, erythropoiesis, and megakaryopoiesis should be adequate without dysplastic features. Increased blasts are not observed. Eosinophil cytologic abnormalities tend to not be as prominent as they are described in CEL, NOS.

Immunophenotype

There are no specific immunophenotypic abnormalities. It should be noted that an exhaustive exclusion of all possible primary clonal eosinophilic conditions and secondary reactive conditions is needed. This may include a variety of immunohistochemical and flow cytometry studies, as discussed in the section on CEL, NOS. A T-cell workup to rule out a T-cell lymphoma or Th2 type T-cells associated with lymphocyte variant of HES is essential before assigning a case of HES as idiopathic. Detection of abnormal mast cells should prompt a diligent search of clonal eosinophilia, though a partial/weak expression of one of the markers, either CD25 or CD30, may be observed on reactive mast cells.[113]

Genetics/Molecular Findings

There are no recurring and/or specific genetic findings in iHE/iHES aside from a possible CHIP mutation. As discussed in CEL, NOS, the presence of a convincing chromosomal abnormality and/or mutations by NGS would support a diagnosis of CEL, NOS rather than iHE/iHES.

Clinical Course

In studies in which an overt hematopoietic neoplasm (such as CEL, NOS, hypereosinophilia associated with a myeloid neoplasm, and myeloid/lymphoid neoplasm with a TK gene fusion) is excluded, patients with iHES showed a more benign clinical course with a disease-related mortality rate around 10% to 15% in the long-term follow-up.[26,107,114,115] Mortality is related to an older age (>60 years), cardiac involvement, cytopenia (anemia or thrombocytopenia), a low absolute lymphocyte count, an increased neutrophil-to-lymphocyte ratio,[115] and hepatosplenomegaly.

For patients with iHES, corticosteroids are effective in producing a rapid reduction in eosinophil count or tissue/organ dysfunction in the majority of cases.[116,117] Resistance or intolerance to steroid treatment occurs in about 20% of patients. Long-term treatment with steroids to suppress eosinophilia and organ damage may carry significant side effects. For patients who cannot tolerate or fail corticosteroid treatment, other agents such as an IL-5 antagonist (mepolizumab)[118] have been shown to significantly reduce the occurrences of symptom flares.

Differential Diagnosis

iHE/iHES are diagnoses of exclusion and require a comprehensive morphologic, clinical, laboratory, and genetic testing approach to exclude reactive etiologies and differential diagnoses such as iHE/iHES, the lymphocytic variant of hypereosinophilic syndrome, T-cell/B-cell lymphoma, Hodgkin lymphoma, AML with inv(16) or CML, and M/LN-eo-TK.

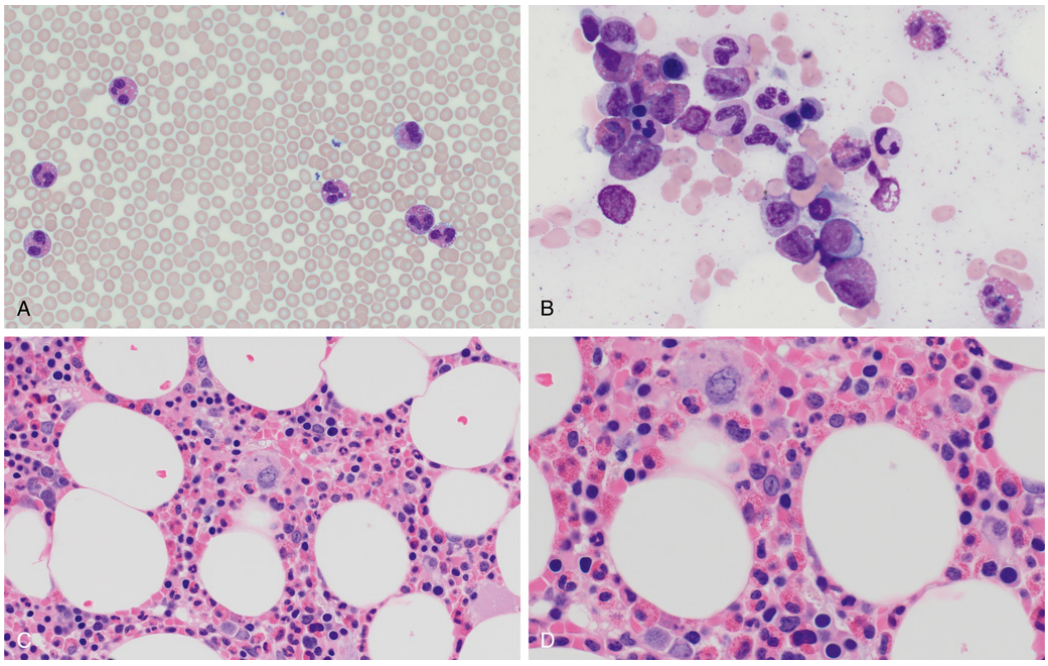

FIGURE 50-13 Idiopathic hypereosinophilia syndrome.A, The peripheral blood smear, by definition, will demonstrate hypereosinophilia with, most often, only occasional forms showing abnormal eosinophil cytology. As seen here, most of the eosinophils are normally granulated and segmented; occasional vacuolization is seen (1000× magnification, Wright-Giemsa). **B,** Bone marrow aspirate smears are spicular and cellular with predominantly normal-appearing eosinophils, which are increased in number. Dyserythropoiesis, dysgranulopoiesis, and dysmegakaryopoiesis are absent. Monocytes and blasts are not increased (1000× magnification, Wright-Giemsa). **C,** The bone marrow core biopsy is typically normocellular/slightly

hypercellular, corresponding to the increase in eosinophils and precursors. The distribution of erythroid and granulocytic precursors is normal, and megakaryocytes exhibit normal morphology (600× magnification, H&E [hematoxylin and eosin]). **D,** The bone marrow core biopsy, on higher power magnification, demonstrates a predominantly interstitial increase in unremarkable-appearing eosinophils (1000× magnification, H&E [hematoxylin and eosin]).

Conclusion

The eosinophilic disorders are a complex group of entities of diverse and vastly heterogeneous etiologies. As such, an integrated approach that evaluates clinical, laboratory, morphologic, genetic, and immunophenotypic features may be required in the simultaneous pursuit and exclusion of a specific diagnosis. With the specific diagnosis/cause identified, the case can be managed appropriately. If a specific diagnosis is not identified, the case should be considered as iHE or iHES, depending on the absence or presence of end-organ damage, respectively.

In cases of M/LN-eo-TK (rearrangement of *PDGFRA, PDGFRB, FGFR1, JAK2,* or *FLT3* or with *ETV6*::*ABL1*), it is important to remember that the clinical presentations are heterogenous and often complex (combined acute and chronic components), extramedullary disease is frequent, eosinophilia is not uniformly present, and the genetic abnormality may be cytogenetically and/or FISH cryptic. As

such, a heightened awareness to these distinct entities and their presentations is required of both clinicians and pathologists, and targeted genetic testing should be considered, as appropriate. In addition, if a particular case does not fit or exemplify the typical pathologic or genetic profile of a usual ICC-defined entity (e.g., CMML), these recurring genetic abnormalities should be considered.

CEL, NOS is a diagnosis of exclusion, and appropriate morphologic, clinical, laboratory, and genetic evaluation is necessary to exclude differential diagnostic considerations. In particular, the presence of abnormal bone marrow morphologic findings and/or convincing molecular genetic/cytogenetic mutations allows for a diagnosis more definitive than iHE/iHES.

Acknowledgments

The editors and author would like to gratefully acknowledge the excellent prior work and authorship on this chapter by Dr. Barbara Bain.

Pearls and Pitfalls

- Eosinophilia encompasses a complex group of disorders of diverse etiology for which there are many tools available for the workup and diagnosis.
- The classification of eosinophilic diseases should reference whether they are reactive or clonal and connote the specific etiology, when possible.

- Given the many causes of eosinophilia, presenting signs and symptoms may vary, including weight loss, fever, cytopenia(s)/cytosis, and cutaneous, pulmonary, cardiac, gastrointestinal and/or central nervous system involvement or newly emerging lymphadenopathy, hepatomegaly, or splenomegaly.
- Secondary eosinophilia is much more common than primary eosinophilia, and the diagnostic workup often involves consultation with multiple medical specialties, including allergy, hematology, pulmonary, infectious disease, rheumatology, and gastroenterology.
- In myeloid/lymphoid neoplasms with eosinophilia and rearrangements of *PDGFRA,* there is a marked male predominance with a male-to-female ratio of approximately 17:1. The median age at presentation is in the late 40s. The majority of these cases (approximately 90%) are chronic and myeloid in nature and carry the *FIP1L1*::*PDGFRA* fusion. Patients with *PDGFRA* fusion respond remarkably well to imatinib TKI therapy.
- Myeloid/lymphoid neoplasms with eosinophilia and rearrangements of *PDGFRB* show a slight male predominance with a male-to-female ratio of 2:1. The median age at presentation is in the 40s. Though CEL-like or CMML presentations tend to predominate, it is important to recognize that there may be other clinical presentations such as B-ALL and, less commonly, AML, T-ALL, or myeloid sarcoma. The majority of cases carry t(5;12)(q32;p13.2) with formation of an *ETV6*::*PDGFRB* fusion. *PDGFRB* with partner

genes other than *ETV6* may be cryptic. Similar to cases of *PDGFRA,* cases with *PDGFRB* respond remarkably well to imatinib TKI therapy, with long-term hematologic and molecular responses.

- In myeloid/lymphoid neoplasms with eosinophilia and rearrangement of *FGFR1,* there is a slight male predominance with a male-to-female ratio of approximately 1.5:1. The median age at presentation is in the 30s to 40s. The disease is well-known for its heterogenous and complex presentations, including CEL, MDS/MPN, AML, T-ALL, or (less often) B-ALL or mixed-phenotype acute leukemia, with frequent eosinophilia and extramedullary disease. *FGFR1* rearrangements are not cytogenetically cryptic. *RUNX1* is highly mutated (>70%). The overall clinical outcome is aggressive. *FGFR1*-rearranged neoplasms do not respond to first-generation TKI therapy but have shown benefit from FGFR inhibitors or third-generation TKI.
- In myeloid/lymphoid neoplasms with eosinophilia and *PCM1*::*JAK2* and genetic variants, the median age at presentation is 50 years with a wide age range, and there is a male predominance (>3:1 male-to-female ratio). Patients typically exhibit hepatosplenomegaly. These neoplasms show a heterogenous presentation ranging from MPN and MDS/MPN (approximately 60%) to AML and B-ALL; extramedullary disease involvement is common. The bone marrow in *PCM1*::*JAK2* shows a typical histopathologic "triad," which includes hypercellularity with an eosinophilic infiltrate, large aggregates of immature erythroid precursors

(pronormoblasts), and myelofibrosis. *PCM1*::*JAK2* is often not cryptic. *ETV6*::*JAK2* and *BCR*::*JAK2* have been recognized as two genetic variants. These lesions show limited benefit from JAK2 inhibitor therapy.

- In myeloid/lymphoid neoplasms with eosinophilia and *FLT3*-rearrangement, the disease appears to be slightly more common in men, with a male-to-female ratio of approximately 1.4:1. There is a broad age of presentation, with the median age in the 50s. The pathologic presentation is heterogenous, including as a CMN (CEL-like, CMML-like, aCML, myelodysplastic syndrome), a higher-grade myeloid disorder with excess blasts, an acute leukemia (T-ALL, B-ALL, and myeloid sarcoma), or a mixed lineage neoplasm (mixed phenotype acute leukemia). The genetic alteration *ETV6*::*FLT3* is typically not cryptic in conventional chromosomal analysis, and involvement of the *FLT3* gene should be considered in cases of a hematopoietic neoplasm in which 13q12 is rearranged. However, alternate partner genes can be cryptic. These cases tend be associated with an aggressive clinical course or early disease progression. Cases, especially those in the chronic phase, often respond to FLT3 inhibitor therapy, though some of the responses may be short-lived.
- In myeloid neoplasms with eosinophilia and *ETV6*::*ABL1,* there appears to be a slight male predominance, with a male-to-female ratio of 2:1. The median age at presentation is in the 5th decade of life. Patients with *ETV6*::*ABL1* rearrangement typically present with a clonal myeloid proliferation and

eosinophilia (sometimes basophilia), most often in chronic phase. There is a known response to TKI treatment.

- In cases without a clear-cut clonal genetic abnormality diagnostic of CEL, NOS (i.e., negative or possible CHIP), clinical and morphologic features may be helpful to distinguish CEL, NOS from iHE/iHES. The bone marrow in patients with CEL, NOS is dramatically hypercellular because of a proliferation of granulocytes and eosinophils. Megakaryocytes are almost invariably abnormal. In contrast, the bone marrow in patients with iHES is unremarkable except for increased eosinophils.
- A heightened awareness of these distinct entities and their occasional complex presentations is required of both clinicians and pathologists, and targeted genetic testing should be considered, as appropriate.

Definition

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a rare aggressive hematologic malignancy characterized by the clonal proliferation of immature plasmacytoid dendritic cells (pDCs), also known as natural interferon type I–producing cells[1] or their precursors. Nomenclature widely varied over time, reflecting the uncertainty of its histogenesis, including *agranular CD4$^+$ natural killer (NK) cell leukemia, blastic NK cell leukemia/lymphoma, agranular CD4$^+$, CD56$^+$ hematodermic neoplasm,* and *tumor, blastic NK-cell lymphoma.*[2-6] On the evidence of its relationship to pDCs,[7-11] the term *blastic plasmacytoid dendritic cell neoplasm* was introduced in the 2008 World Health Organization (WHO) classification (4th edition),[12] where it was included within the acute myeloid leukemia (AML)–related precursor neoplasms; in the 2017 WHO 4th updated edition,[13] BPDCN was classified as an entity distinct from AML, as it remains in the 2022 ICC classification.[14] In contrast, the proposed WHO 5th ed. includes BPDCN in the *histiocytic/dendritic cell neoplasms* category.[15]

BPDCN typically occurs in elderly men, in good states of health, with skin lesions associated with involvement of other sites, mainly bone marrow, lymph nodes, and peripheral blood (**Box 51-1**). Morphologically, the tumor cells show immature features, and immunophenotyping is mandatory for diagnosis. Despite the improvement of knowledge on tumor cell biology and of treatment strategies, prognosis remains poor.

Revised WHO 4th ed.: Blastic Plasmacytoid Dendritic Cell Neoplasm

Proposed WHO 5th ed.: Blastic Plasmacytoid Dendritic Cell Neoplasm

Epidemiology

BPDCN is rare, accounting for <1% of all hematologic malignancies[8,16,17]; according to SEER-18 data, the incidence in the United States is 0.04 cases per 100,000 individuals,[18] with a significantly higher frequency in Caucasians,[18] in contrast to other reports where no ethnic prevalence was found.[8] The male-to-female ratio is about 3 to 4:1, and the median age at diagnosis is 67 years.[18-24] Women are generally 8 to 10 years younger than men and, interestingly, they do not show a significant age peak of occurrence, in contrast to males in which a marked increase from the 5th decade on is observed.[21] About 5% of BPDCN patients are younger than 10 years old[21]; in a survey of 219 cases, 26.9% of patients were less than 20 years old, determining a bimodal pattern of age distribution.[18]

Etiology

Epstein-Barr virus (EBV) and other lymphotropic viruses (human immunodeficiency virus, hepatitis C virus, human herpesvirus 6 and 8, cytomegalovirus, human T-lymphotropic virus 1 and 2) are negative.[8]

The occurrence of BPDCN as secondary leukemia in patients with other myeloid neoplasms, especially myelodysplastic syndrome

(MDS) and chronic myelomonocytic leukemia (CMML) or even solid tumors,[25-29] supports the hypothesis that exposure to therapy may represent a pathogenic factor for BPDCN development, and that BPDCN represents a second event in a context of MDS.[26,30-33] Furthermore, clonal hematopoiesis is highly prevalent in BPDCN patients beyond an associated diagnosis of MDS/CMML,[34,35] suggesting that the earliest events in BPDCN pathogenesis occur in hematopoietic progenitor cells, which subsequently seed peripheral sites during full-blown malignant transformation.[35]

Box 51-1 Foremost Diagnostic Features of Blastic Plasmacytoid Dendritic Cell Neoplasm

- Diffuse skin infiltrate composed of medium-sized immature cells, resembling lymphoblasts or myeloblasts
- Absence of necrosis and angioinvasion
- Positivity for CD4, CD56, and the plasmacytoid dendritic cell (pDC)–associated antigens CD123, TCL1, CD303, TCF4
- Negativity for lineage-associated antigens for T cells (CD3), B cells (CD19, CD20, PAX5), natural killer (NK) cells (CD16, TIA-1, perforin), myelomonocytic cells (myeloperoxidase, lysozyme, CD11c, CD14, CD163), and CD34
- Frequent occurrence of multiple chromosomal abnormalities and mutations, but none of them specific
- Germline configuration of B-cell and T-cell receptor genes

An early pathogenetic event may depend on *ETV6* anomalies, because a high rate of monoallelic and biallelic 12p13/*ETV6* deletions have been found in the bone marrows of BPDCN patients without detectable disease.[36] Ceribelli et al. identified that the E-box transcription factor TCF4 (also known as *E2-2*), a key regulator in the committed development of pDCs from common dendritic cell progenitors,[37] plays a master regulatory role in BPDCN cells and can be regulated by the bromodomain and extraterminal domain (BET) protein BRD4.[38] IKZF1 inactivation was found as a key event in the development of BPDCN.[39]

Clinical Features

The clinical features and evolution of BPDCN are rather homogeneous[5,8,9,17,19,22,23,40-44] and consist of two main patterns, one (70%–90% of cases) dominated by skin lesions followed by tumor dissemination, the other (10%–30%) by skin lesions, acute leukemia, and systemic involvement from the beginning. The interval between the onset of lesions and diagnosis is variable, with a mean time of 6.2 months (range 2–18 months), a delay likely depending on the rarity of the disease and poor knowledge by both clinicians and pathologists.[22]

Skin lesions are usually asymptomatic and sometimes last for months.[22,45] Patients are in good general health without systemic symptoms, concealing the aggressive nature of the underlying disease; however, they usually show pancytopenia and leukemic cells in the blood. In about 30% to 50% of cases, skin lesions are the only detectable clinical manifestation.[5,17,22,23,40,41] In a series of 398 patients, the skin was involved at diagnosis in 89% of cases, as

unique site (30%) or associated with disseminated disease (57%), while disseminated noncutaneous disease occurred in 13% of cases.[19]

Skin lesions can be single, but usually are multiple; they can involve any body site, appear as reddish to bluish nodules, plaques, or bruiselike areas, with size variability from a few millimeters to several centimeters (**Fig. 51-1**).[8,22,41,44,46] At presentation, bone marrow involvement occurs in 50% to 90% of cases and it is mostly extensive[47]; when minimal, it invariably increases with disease progression. Localized or disseminated lymphadenopathy occurs in about 40% to 50% of cases, and splenomegaly and hepatomegaly in 9% to 25% and 6% to 17 of cases, respectively.[5,8,19,22,23] Uncommon affected sites include oral mucosa, lung, tonsils, soft tissue, and eyes.[22,48]

Circulating tumor cells are found in about 50% to 70% of the patients, generally with low counts at presentation.[23,25,42,45,49,50] The "leukemic" BPDCN variant is characterized by an elevated white blood cell count with blasts and massive bone marrow infiltration,[23,25,26,50-52] and it is generally associated with multiple skin lesions as well.[42] Cases showing a "pure" leukemic presentation are rare, occur in individuals with younger age (median, 52 years), and are frequently associated with splenomegaly and lymphadenopathy.[21]

At onset of disease, patients frequently show anemia, thrombocytopenia, and neutropenia,[23] which, in a minority of cases, are severe, indicating bone marrow failure[5,25]; marrow or blood monocytosis can reveal the co-existence of a myeloid neoplasm.[5,23] In about 15% to 20% of patients, BPDCN is associated with CMML,

MDS, or AML, which may precede, concur, or follow BPDCN.[5,9,10,17,22,25-29,44,53-57]

The frequency of central nervous system (CNS) involvement is probably underestimated because of the lack of systematic application of cerebrospinal fluid testing in BPDCN patients.[58] At diagnosis, overt or occult CNS involvement has been reported in 8% to 60% of patients, even asymptomatic,[22,23,40,58,59] and frequently occurs at relapse.[25,26,58,59]

Morphology

BPDCN tumor cells morphology varies from medium-sized pleomorphic blasts with irregular elongated, twisted nuclei, to small-to-medium-sized cells resembling lymphoblasts; chromatin is finely dispersed and the nucleoli, when present, are small, single, or multiple, except in the immunoblast-like variant associated with *MYC* gene rearrangement.[60] The cytoplasm is scant and difficult to visualize; on Giemsa stain it appears gray-blue and devoid of azurophilic granules. Mitotic activity is markedly variable, as is the Ki-67 expression (20%–80%) (**Fig. 51-2A–C**).[44,53,61,62]

In skin biopsies, the tumoral infiltrate predominantly involves the dermis, often extending to the subcutaneous fat; epidermis and adnexa are spared, with rare exceptions; angioinvasion and coagulative necrosis are generally absent (**Fig. 51-3A**).[44] Tumor-associated inflammatory cells are scant and mainly represented by T lymphocytes and scattered macrophages.

Lymph nodes are initially infiltrated in the interfollicular areas and the medulla, sparing B follicles (**Fig. 51-3B**). The bone marrow is usually involved with high tumor load (**Fig. 51-3C**); when sparse, it

is only detectable by immunohistochemistry,[63,64] although the presence of reactive pDCs may cause false positivity and analysis of the marrow aspirate using flow-cytometry is preferrable in these cases.[65]

On blood or marrow smears, tumor cell morphology is quite heterogeneous.[23] Typical blasts are medium sized with round or irregular, often eccentric, nucleus; small nucleoli; and a faintly and irregularly basophilic cytoplasm with variability of coloration. Small vacuoles are frequently found arranged under the cytoplasmic membrane, and cytoplasmic pseudopodia occur in a fraction of cells (**Fig. 51-2D**). Blasts with a dominant lymphoid-like features or with immature features including high nuclear-to-cytoplasmic ratio, fine chromatin, and large nucleolus can also occur; in addition, a portion or, more rarely, the entire blast population, displays monoblastic-like features. Despite most cells not showing granules or crystals,[23,25] rare cells with azurophilic fine or large granulations have been detected in a minority of blasts.[23]

FIGURE 51-1 **A–D,** Examples of skin lesions in blastic plasmacytoid dendritic cell neoplasm. Lesions may consist of nodules, plaques, or bruiselike areas, with variable colors. Courtesy of Prof. Lorenzo Cerroni, Graz, Austria; Dr. Stefano Corsico, Brescia, Italy; and Prof. Piergiacomo Calzavara, Brescia, Italy.

In about one-third of cases, residual hematopoietic cells show dysplasia in ≥1 lineages, especially in the myeloid cells and megakaryocytes, and numbers of monocytes can be increased.[17,23,66]

Immunophenotype

The diagnosis of BPDCN is usually made on a skin biopsy or, less frequently, on marrow aspirate and peripheral blood; it is essentially based on immunohistochemistry and flow cytometry analysis.

In the suspicion of BPDCN, the diagnostic approach should comprise diagnosis-supportive and diagnosis-excluding markers, the former including CD4, CD56, and other pDCs' specific antigens CD123, TCL1, CD303, and TCF4, the latter encompassing CD3, CD19, CD20, CD11c, CD14, CD163, lysozyme, and myeloperoxidase (**Table 51-1**) (**Fig. 51-4A–F**).[4,8,10,19,21,23,25,29,38,43,44,57,60-62,67-72]

CD123, recognizing the interleukin-3 receptor alpha chain, is positive in the majority of BPDCN,[4,19,44,62,73] in association with CD4 and CD56 in 87% to 96% of cases.[19,21] High levels of TCL1 are found in 80% to 85% of cases, mostly in association with CD4, CD56, and CD123.[19,44,46,47,54,62,72,74-76]

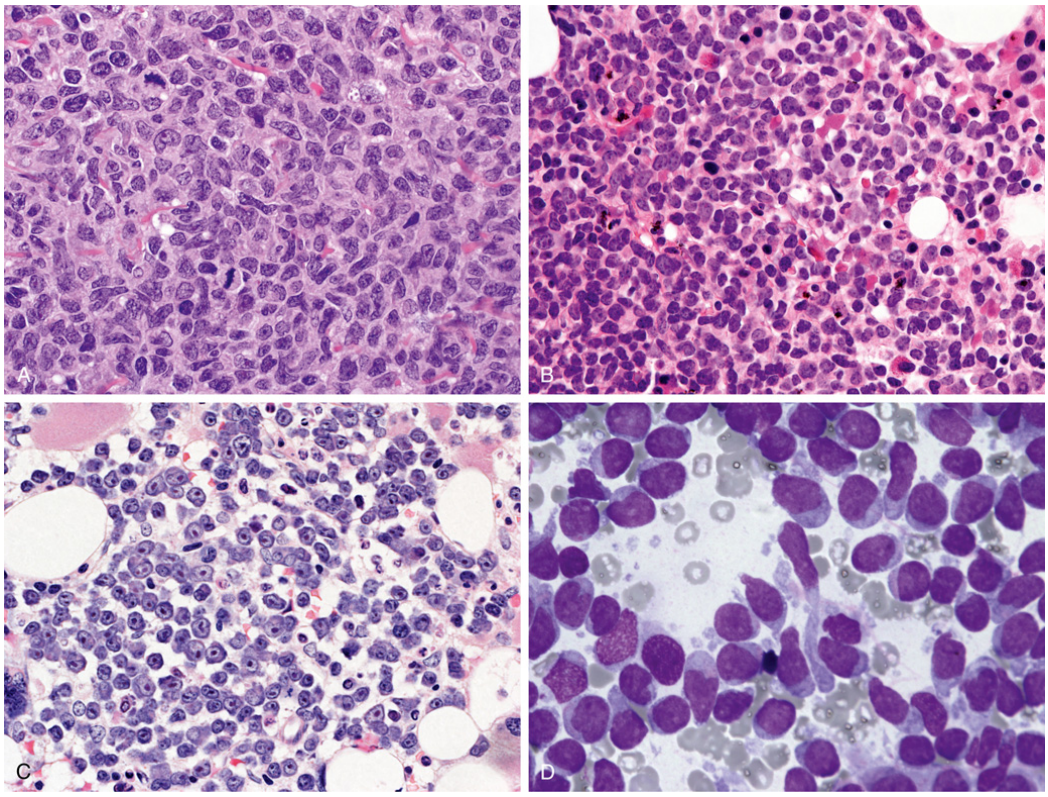

FIGURE 51-2 The cytomorphology of the immature tumor cells in blastic plasmacytoid dendritic cell neoplasm varies from medium-sized pleomorphic blasts with irregular elongated twisted nuclei **(A)** to lymphoblast-like cells **(B)** to immunoblast-like cells **(C)** (hematoxylin-eosin). In bone marrow aspirate **(D)**, tumor cells show a blastic appearance and pseudopodia-like extensions of the cytoplasm, which may be irregularly basophilic and contain small peripheral vacuoles.

CD303 recognizes the BDCA-2 antigen and represents a high specific marker for BPDCN,[55,70,71] but its sensitivity varies according to series from more than 70% of cases[8,10,19,21,61,70,71] to significantly

lower values.[49,57,62,69,72] It cannot be excluded that this variability may depend on the reagent applied, the substrate used (fresh-frozen versus formalin-fixed tissue) or the degree of differentiation or activation of tumor cells.[65]

TCF4 (also known as *E2-2*) has been shown to have high specificity and sensitivity for BPDCN,[38,46,77] alone or in combination with CD123 (**Fig. 51-4E**).[72]

Additional markers expressed in normal/reactive pDCs have been found to be useful to support the diagnosis of BPDCN, such as MX1,[10,62,75,77] CD2AP,[73] BCL11a,[78] SPIB,[79] and E-cadherin.[77] In contrast, CD68 and granzyme-B, two molecules usually strongly expressed by pDCs,[80,81] are respectively positive in about half of BPDCN cases with a cytoplasmic dot pattern (**Fig. 51-4H**),[4,17,19,44,62,67] or completely negative.[4,19,67]

Terminal deoxynucleotidyl transferase (TdT) is expressed in about one-third of cases in 10% to 80% of tumor cells.[3,4,43,67,73] CD117 can be positive, while CD34 has consistently been reported negative (**Fig. 51-4F–G**).[10,17,50,67]

In addition to CD56, BPDCN can express markers generally lacking in normal pDCs, such as BCL2 (**Fig. 51-4I**), BCL6, and S100 protein[9,19,55,70]; positivity for myeloid or lymphoid markers, including CD2, CD5, CD7, CD22, CD33, and cCD79a[19,60,62,82] can make the diagnosis of BPDCN sometimes complex.[66]

A confident BPDCN diagnosis can be made when tumor cells are positive for at least four among CD4, CD56, CD123, CD303, and TCL1,[62] or when positivity for CD4 and CD56 is associated with ≥1 among CD123, TCL1, and BDCA2/CD303 and negativity of lineage-specific markers for myeloid cells (myeloperoxidase), T cells (CD3),

B cells (CD20), and monocytes (CD11c, CD163, lysozyme).[19] According to the proposed WHO 5th ed., immunophenotypic diagnostic criteria include the expression of CD123 and one among the pDC markers TCF4, TCL1, CD303, and CD304, or positivity of any three pDC markers and negativity for all expected negative ones (CD3, CD14, CD19, CD34, lysozyme, and myeloperoxidase).[15]

On flow cytometry, tumor cells occur in the low-side scatter blast-gate with dim expression of CD45.[49,50,83] Comparing 20 cases of BPDCN and 113 lymphoid and myeloid acute leukemias, it has been defined a BPDCN diagnostic score with a minimum value of 3 obtained from four parameters including CD4 positivity (not necessarily CD56) plus negativity of myeloperoxidase, cCD3, cCD79a, and CD11c (score = 1), CD123 positivity (score = 1), CD303 positivity (score = 2), and CD304 positivity (score = 1).[49]

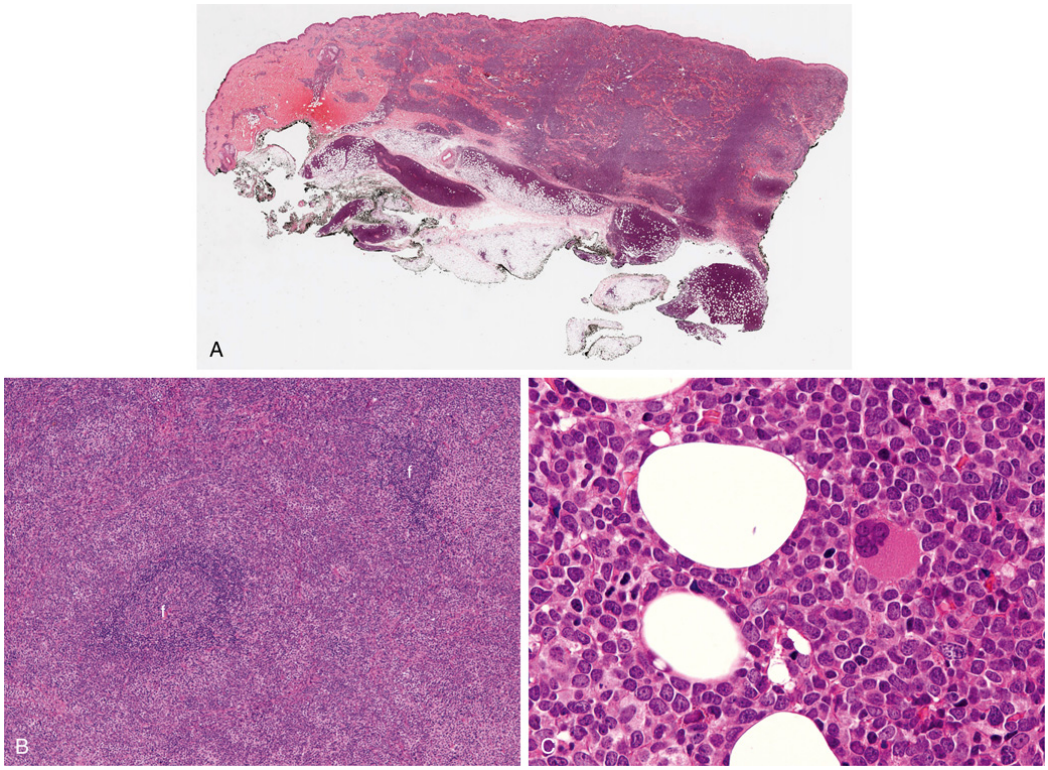

FIGURE 51-3 Blastic plasmacytoid dendritic cell neoplasm (BPDCN) involving the skin **(A)**, lymph node **(B)**, and bone marrow **(C)**. In the skin **(A)**, the infiltrate spares the papillary dermis and diffusely involves the dermis, extending to the subcutaneous fat. In the lymph node **(B)**, BPDCN obliterates the interfollicular and paracortical areas, sparing follicles *(f)*. Bone marrow **(C)** is usually extensively replaced by tumor cells.

Table 51-1

Comparison of Immunohistochemical Markers Expressed in Paraffin Sections by Normal Plasmacytoid Dendritic Cells and Blastic Plasmacytoid Dendritic Cell Neoplasm Tumor Cells

Expression	Markers
Positive in normal pDCs and in BPDCN	CD4, CD43, CD45RA, CD68,* CD123, CD303, CD2AP, SPIB, TCF4, TCL1, BCL11a, MxA
Negative in normal pDCs and positive in BPDCN	BCL2, CD2, CD7, CD33, CD38, CD56, CD79a, CD117, TdT[S100†]
Negative in normal pDCs and in BPDCN	CD1a, CD3, CD8, CD11c, CD13, CD14, CD16, CD19, CD20, CD21, CD23, CD25, CD30, CD34, CD45R0, CD57, CD138, immunoglobulin (surface and cytoplasmic), Langerin/CD207, lysozyme, myeloperoxidase, MNDA, PAX5, perforin, TCR-AB and TCR-GD, TIA-1

BPDCN, Blastic plasmacytoid dendritic cell neoplasm; *MNDA,* myeloid nuclear differentiation antigen; *pDC,* plasmacytoid dendritic

cell; *TCR,* T-cell receptor; *TdT,* terminal deoxynucleotidyl transferase.

* In normal PDCs, CD68 expression is constantly diffuse in the cytoplasm, while in BPDCN, expression may be negative or positive with dot-lite expression.

† The expression of all these markers except CD56 is variable in BPDCN.

Similarly to immunohistochemistry, cytofluorimetry has highlighted the frequent and even combined expression of markers from myeloid, B-lymphoid, and T-lymphoid lineages, excluding myeloperoxidase, CD14, cCD3, CD19, and cCD22.[23,65] Accordingly, a more detailed BPDCN diagnostic flow chart includes as admission criterion the negativity for specific lineage markers (CD3, CD19, cCD22, myeloperoxidase, CD14, CD11c, and CD64), regardless of expression of isolated or associated less-specific lineage markers (e.g., CD7, CD2, CD33, CD13, CD117, CD22, and cCD79a), followed as supportive criterion by the high expression of CD123 and HLA-DR, plus CD4 and CD56 (which can be negative), and for final confirmation by the positivity for cTCL1, CD303, and CD304.[23] To note, the level of CD4, CD56, and CD303 is frequently lower compared with normal T cells, NK cells, and reactive pDCs.[23,65] Because reactive pDCs may co-exist with BPDCN in the bone marrow, including a small subset positive for CD56, CD2, and CD38,[65] a 10-color flow cytometric panel has been applied to distinguish reactive from neoplastic pDCs and to identify with a sensitivity up to 0.01% BPDCN minimal residual disease in patients under treatment.[65]

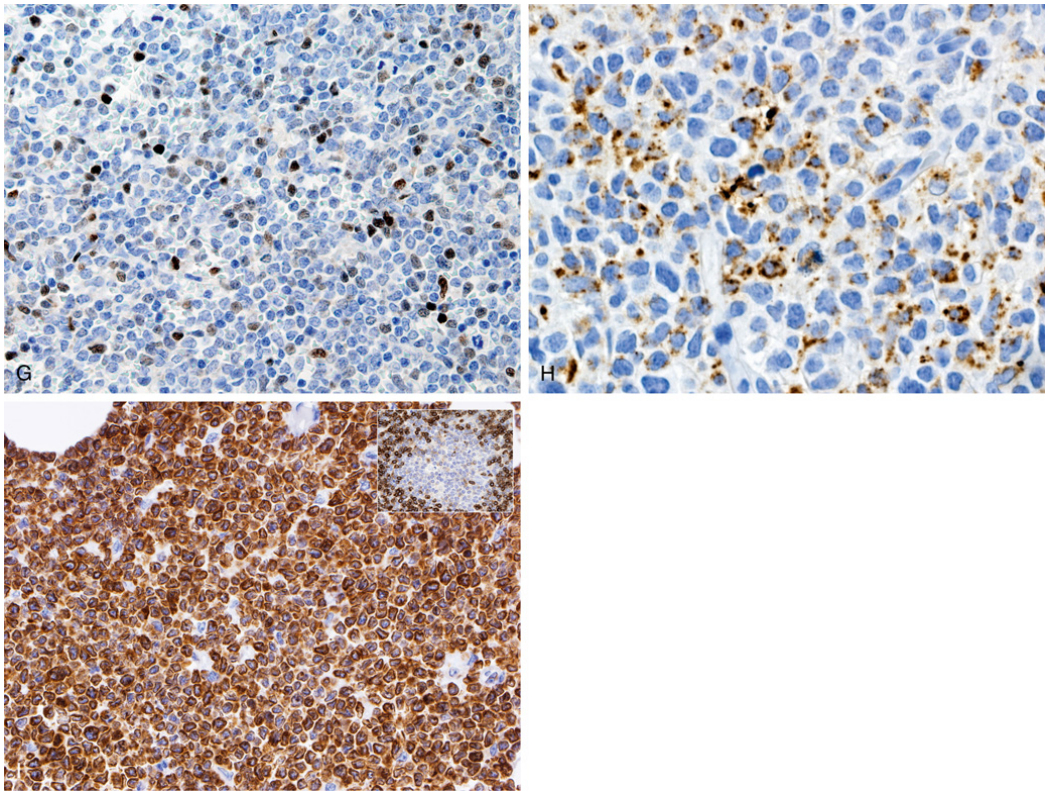

FIGURE 51-4 Immunohistochemical features of blastic plasmacytoid dendritic cell neoplasm. Positive tumor markers are represented by CD4 **(A)**, CD56 **(B)**, CD123 **(C)**, and TCL1 **(D)**, respectively. Tumor cells in bone marrow biopsies show co-expression of CD123 (cell membrane, *brown*) and TCF4 (nucleus, *blue*) **(E)**; they are CD303-positive (cell membrane, *brown*) and negative for CD34 *(blue)* **(F)**.**G,** Terminal deoxynucleotidyl transferase is variably expressed. **H,** CD68 is typically expressed in the form of dotlike positivity. **I,** BCL2 is strongly positive; compare with the negativity of a reactive plasmacytoid dendritic cells (pDCs) cluster *(inset)*.

Cytochemistry

BPDCN tumor cells are nonreactive for alpha-naphthyl butyrate esterase, naphthol AS-D chloroacetate esterase, and peroxidase cytochemical reactions.[9,23,25,53]

Genetics and Molecular Findings

T-cell and B-cell receptor gene are usually germline[9,17,43]; the rearrangement of the T-cell receptor gamma observed in few cases[5,17,23,29,84,85] may depend on clonal bystander T cells or T-cell clonotype expansion.[86]

Recurrent and usually multiple (≥3) chromosomal alterations occur in the large majority of cases, especially represented by genomic losses of 5q21 or 5q34 (72%), 12p13 (64%), 13q13-21 (64%), 6q23-qter (50%), 15q (43%), and of the entire chromosome 9 (28%), resulting in the defeat of cell cycle–related and tumor suppressor genes such as *CDKN1B, CDKN2A, CDKN2B, RB1, TP53, LATS2,* and *IKZF1*.[9,29,40,67,87-93] Although none of these recurrent alterations are BPDCN-specific, being detected also in other mostly myeloid malignancies, their co-existence, leading to a combination of deletions of several tumor suppressor genes, represents a peculiar genomic feature of BPDCN.

FISH analysis showed frequent rearrangements of the *ETS* variant gene 6 *(ETV6)*,[36] similarly to other myeloid malignancies. *MYC* translocations have been detected in 12% to 38% of cases,[94,95] and are associated with high MYC protein expression, immunoblast-like morphology,[60] and a more aggressive behavior.[60,96] The most

prevalent *MYC* rearrangement is t(6;8)(p21;q24),[60,94,96] resulting in a chimeric transcript involving *SUPT3H* (6p21) and *PVT1* 50 kb downstream of *MYC*.[97] Notably, the genomic sequence of *SUPT3H* overlaps with *RUNX2,* a super-enhancer gene highly expressed in BPDCN.[38] Rearrangements of the oncogenic transcription factor *MYB* have been found especially in pediatric or young patients,[60,94,98] with fusions involving different partner genes resulting in the activation of *MYB* target genes. Notably, *MYB* and *MYC* rearrangements do not co-exist in the same tumor, suggesting mutual exclusion of their functions in BPDCN.[60]

On gene expression analysis, BPDCN has a signature distinct from that of acute myeloid and lymphoid leukemias,[82,88,93] with significant enrichment of pDCs-related genes.[82,88,93] A minority of cases, however, have a B-lymphoid origin signature, or signatures of the pDC-like dendritic cells AS-DCs.[99] Compared with normal pDCs, BPDCN downregulates genes encoding type I interferons (IFN), and genes regulating the immune system, signal transduction, and ubiquitination, the most relevant being represented by *GZMB, CLEC4C, NPC1, BCL11A, NPC2, IL10RA, CXCR3, UBE2W,* and *UBE3C*[93]; in contrast, top upregulated genes in BPDCN include cell proliferation and division, such as *IGLL1, GLUL, CLEC11A, UBE2T, BCL6, TLR2, UBE2C, BCL2, LRMP, UBE2S*, and the transcription factor SOX4, the latter involved in pDCs ontogeny and differentiation, and, as upregulator of TCF4[38] appearing crucial for BPDCN oncogenesis.[93] Moreover BPDCN shows overexpression of genes involved in Notch signaling[88] and encoding for cyclin D1 and BCL2, and NF-κB activation.[82,93,100] Cholesterol homeostasis–related genes are downregulated in BPDCN, resulting in cholesterol

accumulation within tumor cells, which can be normalized by treatment with LXR agonists, ensuing NF-κB inhibition and tumor cell apoptosis.[101] Haploinsufficiency of the gene encoding the glucocorticoid receptor *NR3C1* was found in a subset (13/47, 28%) of cases with a balanced t(3;5)(q21;q31) translocation, resulting in the fusion of *NR3C1* with a long noncoding RNA gene *(lincRNA-3q)* involved in the regulation of leukemia stem cell programs and G1/S transition via E2F. The consequent overexpression of *lincRNA-3q* consistently present in malignant cells can be abrogated by BET protein inhibition and may explain the high aggressiveness of this subset of tumors.[102] Similarly, tumor aggressiveness may be explained by neural features found in BPDCN, with overexpression of multiple neural receptors that stimulate tumor proliferation and migration.[93,103]

The majority of BPDCN are characterized by multiple but not specific mutations. They most frequently involve *TET2* (36%–80%) and *ASXL1,* often co-existing in the same tumor. Similarly to the cytogenetic landscape, the BPDCN mutational profile is close to that found in myeloid neoplasms, mostly influencing the epigenetic program (*TET2, ASXL1, EZH2, ATRX, IDH1, IDH2, DNMT3A, IKAROS* family, *SUZ12, ARID1A, PHF2, CHD8*), the *RAS* pathway *(NRAS, KRAS)*, splicing *(SF3B1, SRSF2, ZRSR2)*, and tumor suppression control *(TP53, RB1, ATM)*.[29,34,40,91-93,104-107] Loss-of-function mutations of *ZRSR2* on X chromosome (Xp22.2) are enriched in BPDCN and nearly all occur in males, which might explain the striking male predominance of BPDCN.[108] Clonal evolution of BPDCN is characterized by additional mutations occurring during disease progression or in different sites.[35,40,109,110]

Notably, mutations that are frequently found in AML, like *FLT3-ITD* and *NPM1,* have been rarely observed in BPDCN.[19,34,40,92,106,111]

Postulated Cell of Origin and Normal Counterpart

On the basis of shared immunophenotypic (**Fig. 51-5A–D**) and molecular features pDCs precursors have been considered to represent the cell of origin of BPDCN.[4,5,7,8,10,11,23,38,54,61,69,74,82,88,93,112,113] **Box 51-2** lists the main morphologic and phenotypical features of pDCs and their involvement in human diseases.

The definition of the nature and functions of pDCs has been a long and controversial process, testified by the heterogeneous terms proposed over time, such as *lymphoblast*, *T-associated plasma cell*, *plasmacytoid T cell*, *plasmacytoid monocyte*, *natural interferon type I–producing cells,* and *plasmacytoid dendritic cell*, the last two likely representing the essential properties of pDCs, the rapid and massive production of type I interferons (IFN-I) in response to viruses, and the ability to differentiate into classical dendritic cells (cDCs).[1,114-116]

A novel subset of dendritic cells has been identified in mice and humans, showing expression of AXL and SIGLEC6 and defined AS-DCs.[99] AS-DCs share with pDCs CD123^{high}, HLA-DR^{high}, and CD303 (hence the alternative term *pDC-like DCs*),[117] and similarly to pDCs, they are absent from normal skin.[118,119] The AS-DCs differ from canonical pDCs by the expression of classical DC markers (e.g., CD2, CD33, CD5, CD86) and some B-cell features (IGLL11, SIGLEC11, CD221, LYZ1).[99,117,119-121] Moreover, they show pDC- and cDC-like

enriched signatures, are characterized by low IFN secretion but high ability to stimulate T-cell proliferation, thus having a transition state from pDCs to cDCs. It has been suggested that the T-cell stimulatory capacity of pDCs isolated with standard markers (e.g., CD123 and CD303) may depend on the AS-DCs fraction, thus indicating that pure pDCs correspond more closely to the *natural type I interferon-producing cells*.[99]

In a recent series of 13 BPDCN cases, about half showed a canonical pDC-like signature, while the remaining revealed expression of SIGLEC6, supporting an AS-DCs origin, as also supposed for the CAL-1 BPDCN cell line.[93] Therefore, BPDCN might have a heterogeneous ontogeny, with derivation either from canonical pDCs or from AS-DCs. Nevertheless, the lack of IFN-I production or defective IFN-I signature reported in BPDCN[82,93,122,123] can be unrelated to the cell of origin, but to oncogenic events, such as IFN-I gene loss,[93] functional status, or inhibitory mechanisms.[77,124]

pDC development can derive from a common myeloid progenitor through a common dendritic cell precursor or from either myeloid or lymphoid progenitors.[117,125-129] The myeloid-like mutational landscape observed in the majority of BPDCN and its association with myeloid neoplasms with shared mutations suggest that a significant percentage of BPDCN originate from a myeloid precursor. Yet a lymphoid-like origin of BPDCN is supported by overexpression of lymphoid-related genes and occurrence of lymphoid-type mutations,[92,93] as well as *IKZF1* abnormalities[39] normally absent in myeloid neoplasms. Thence, an evolutionary theory of BPDCN has been proposed, in which in the preleukemic phase pDCs or AS-DC

precursors display low-variant allele frequency (VAF) myeloid-type mutations related to clonal hematopoiesis, followed during disease progression by the occurrence of additional oncogenic events, including lymphoid abnormalities and pan-cancer mutations.[93]

Clinical Course and Prognosis

Despite the deceptively indolent clinical presentation with initial response to a variety of intensive chemotherapy regimens, the course is almost invariably aggressive, with a median survival of 10 to 24 months, not significantly improved during years.[5,8,17-19,22-26,34,44,45,51]

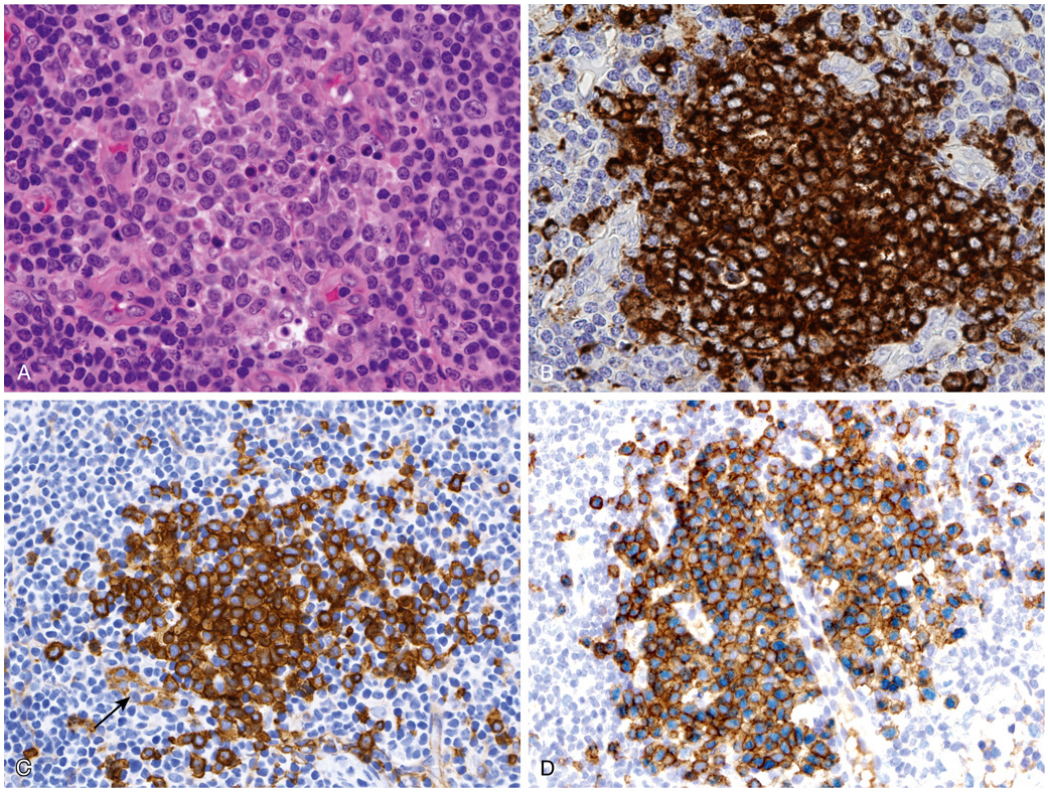

FIGURE 51-5 **P**lasmacytoid dendritic cell cluster in a reactive lymph node.The cytomorphology **(A)** and markers typically expressed on plasmacytoid dendritic cells (pDCs) are illustrated: CD68 **(B)**, CD123, which also stains high endothelial venules *(arrow)* **(C)**, and CD303 and TCF4 (CD303 on the cell membrane, *brown*; TCF4 in the nucleus, *blue*) **(D)**.

Negative prognostic factors include older age,[18,19,23,34,40,70,130] disseminated disease at diagnosis,[19,23] and high blast counts in the bone marrow or peripheral blood.[23,34,42] Better outcome occurs in patients who respond to the first line of treatment and receive hematopoietic stem cell transplantation.[19,23,26,34,40,41,131,132]

Among biological parameters, high TdT expression and Ki67 index[19,42,69] have been associated with better survival, whereas positivity for CD303 had contrasting results.[62,69] The presence and the amount of cytogenetic aberrations do not correlate with prognosis,[19,40,92] while a significantly reduced overall survival is related to a high mutation load,[40] to mutations of genes encoding for epigenetic factors or belonging to the *IKAROS* family and DNA methylation pathway,[40,105] loss of the glucocorticoid receptor gene *NR3C1*,[102] *CDKN2A/CDKN2B* deletions,[90] and *MYC* rearrangement.[60]

At present, there is no consensus on the optimal treatment of BPDCN, but all patients should receive systemic therapy, regardless of the extension of the disease at presentation.[133] Intensive induction leukemia-like regimens achieving complete remission followed by hematopoietic, especially allogenic, stem cell transplantation (allo-HSCT) offers a chance of longer survival.[19,23,25,26,40,131,132,134,135] Unfortunately, only a minority of BPDCN patients are eligible for allo-HSCT and alternative low intensity treatments have been considered, such as single-agent pralatrexate, bendamustine, and gemcitabine/docetaxel combinations, with promising results, though applied in sporadic cases.[136,137]

Differently from adults, in children the current recommendation suggests ALL-type chemotherapy followed by observation, reserving allo-HSCT for relapse and second complete remission.[70,130,138]

In adults and pediatric patients, it has shown frequent CNS involvement and a high rate of CNS relapse of BPDCN, suggesting prophylactic intrathecal chemotherapy.[130,139]

The understanding of the pathophysiology of BPDCN is significantly improved during the last years and prompted to identify and apply novel target-specific agents based on relatively constant biological features of the disease, such as the strong expression of CD123, the extensive epigenetic dysregulation, and the aberrant activation of NF-κB pathway leading to BCL-2 overexpression. For other BPDCN-associated molecular mechanisms (e.g., the highly dependence on TCF4- and BRD4-transcriptional network and the deregulation cholesterol metabolism, especially inactivation of LXRs target genes), the effectiveness of pharmacologic interventions still refers to preclinical models.

Box 51-2 Morphologic and Phenotypical Features of Normal Plasmacytoid Dendritic Cells

Occurrence

- Especially in lymph nodes and tonsils, rare in the thymus (medulla) and other hematopoietic tissues; 0.1% to 0.05% of total peripheral blood leukocytes; very rare in the skin

Morphology

- Typically present in the vicinity of high endothelial venules, as scattered elements or aggregates; the latter typically contain apoptotic bodies
- Medium-sized cell with a single round-oval or indented nucleus, finely dispersed chromatin, and one or two small

nucleoli; moderately abundant eosinophilic cytoplasm, basophilic on Giemsa stain

- No mitotic activity

Immunohistochemical Recognition

- Best markers for plasmacytoid dendritic cell (pDC) identification on paraffin sections: CD123, TCL1, CD303, TCF4

pDCs in Human Diseases

- Marked pDCs increase in lymph nodes in Kikuchi-Fujimoto disease and the hyaline-vascular subtype of Castleman disease
- pDCs play a pivotal role (by secreting high amounts of type I interferon and interacting with other immune cells) in autoimmune diseases, especially systemic lupus erythematosus (SLE) and psoriasis
- In SLE, pDCs accumulate in tissues (e.g., skin)
- pDC function is defective in human neoplasms (e.g., melanoma, ovarian carcinoma, head and neck squamous cell carcinoma)
- pDCs are associated with the local antitumoral and antiviral response to imiquimod, a potent stimulator of TLR-7

The anti-CD123 immunotoxin tagraxofusp (SL-401) has been specifically approved for the treatment of adult and pediatric BPDCN.[140,141] In addition, various CD123 antibody-based drugs have been developed,[137] such as the humanized anti-CD123 drug-

conjugated antibody IMGN632, which has shown to be useful in patients relapsed on prior therapy or after tagraxofusp[139]; the anti-CD123/CD3 bispecific monoclonal antibody XmAb14045, currently being studied in a phase I trial (NCT02730312); and the CD123-specific CAR-T, which has given encouraging results in preclinical and clinical studies.[142] BPDCN treatment using the anti-NF-κB proteasome inhibitor bortezomib, especially in association with other drugs, resulted in discrete but mostly transient responses.[143-145] Similar results have been obtained by using the BCL-2 inhibitor venetoclax,[100] while complete remission even in relapsed/refractory was achieved in BPDCN patients treated with venetoclax and hyper-CVAD regimen[146] or in combinations with hypomethylating agents.[147] The efficacy of hypomethylating agents (e.g., 5-azacitidine) shown in treating BPDCN patients, especially in association with anti-CD123 or anti-BCL2 agents, recently led to a clinical trial with triplet drug combination (NCT03113643).

The treatment of BPDCN remains difficult in obtaining effective and lasting results. Altogether, except for tagraxofusp, data indicate that a single targeted therapy agent is not sufficient to achieve long-term remission, and combination with conventional therapy is necessary.[20] Several clinical trials are ongoing,[139] and they remain the main option for patients not eligible for allo-HSCT or not achieving first-line or second-line complete remission.[133,139]

Box 51-3 Differential Diagnosis of Blastic Plasmacytoid Dendritic Cell Neoplasm

LAT, Linker for activation of T cells; *MNDA,* myeloid nuclear differentiation antigen; *NK,* natural killer; *TdT,* terminal deoxynucleotidyl transferase.

Acute Myeloid Leukemia* and Chronic Myelomonocytic Leukemia

- Positive for myeloperoxidase, lysozyme, CD11c, CD13, CD14, MNDA, and often for CD34

Caveats

- CD4, CD56, and CD123 can be positive in acute myeloid and monocytic leukemia
- CD33 is commonly expressed by blastic plasmacytoid dendritic cell neoplasm (BPDCN)

Precursor Lymphoblastic Leukemia/Lymphoma

- Positive for B-cell and T-cell lineage antigens (e.g., CD19, PAX5, CD3)
- Clonal configuration of B-cell and T-cell receptor genes

Caveats

- Plasmacytoid dendritic cell (pDC) markers CD56, CD2AP, or TCL1 can be positive in T-cell and B-cell precursor lymphoblastic lymphomas
- BPDCN can express CD2, CD7, CD79a, CD117, and TdT, the latter mostly focal and weak

* Especially minimally differentiated, undifferentiated, and monocytic subtypes.

Differential Diagnosis

In most of the cases, the differential diagnosis includes immature ("blastoid") hematologic neoplasms, such as ALL, AML, and myeloid sarcoma (MS) (**Box 51-3**). Notably, all of them can express markers typically used for BPDCN diagnosis. CD4 and CD56 positivity can be found in AML and MS, especially with monocytic differentiation[43,57,74,88]; CD123 is expressed, albeit weakly, in acute B-ALL and T-ALL, and more frequently in AML, even in association with CD4 and CD56.[62,148] TCL1 is expressed in about 20% of AML[43,54,74,149] in addition to mature lymphoid malignancies[150] and T-cell prolymphocytic leukemia.[151]

Thus, as discussed in the immunophenotype section, a panel of markers is required for the definite distinction of BPDCN from mimickers.[21,57,75,76,152] Notably, CD34 is almost never expressed in BPDCN, and E-cadherin has been proven very useful to distinguish BPDCN from leukemia cutis.[77]

BPDCN differential also includes other pDC neoplastic proliferations regularly associated with clonally related myeloid neoplasms, represented by *mature pDC proliferation* (MPDCP)[153-156] and *AML with pDC expansion*.[157-159] In the proposed WHO 5th ed., MPDCP has been recognized as a distinct entity among the pDC neoplasms included in the *histiocytic/dendritic cell neoplasms* category.[15] MPDCP predominantly occurs in elderly males, mostly affected by CMML or, more rarely, by MDS or AML with monocytic differentiation.[57,155,156,160] MPDCP can be accidentally identified on

a bone marrow biopsy control, or in patients developing lymphadenopathy or skin erythematous macules or papules.[57,161-163] Circulating pDCs are very rarely found in MPDCP,[164] except for cases with high (>5%) pDC counts in the bone marrow, which correlates with increased risk of AML transformation and higher incidence of mutations in the *RAS* pathway.[165] A distinctive histologic feature of MPDCP consists of the occurrence of multiple nodular or irregular aggregates of pDCs, mostly occurring in the bone marrow, skin, or lymph nodes, often admixed with the associated myeloid neoplasm (**Fig. 51-6A–D**).[57,153,155,156,160,163,166,167] PDCs exhibit a morphology akin to reactive pDCs, with some variability in nuclear size and contour; the phenotype also overlaps that of reactive pDCs,[165,168] except for occasional aberrant expression of CD2, CD5, CD7, CD10, CD13, CD14, CD15, and CD33.[57,73,155,162,163] In contrast to BPDCN, pDCs in MPDCP express CD68 and granzyme B, and are negative for CD56 and BCL2, although weak CD56 expression sometimes occurs.[57,81] The proliferation index is low (<10% Ki-67) and TdT is negative. On gene-expression analysis, the pDCs in MPDCP are close to healthy donors' pDCs,[165] but their neoplastic nature and relatedness to the associated myeloid neoplasm has been proven by the identification of similar chromosomal abnormalities or mutations.[47,155,162,164,165,167,169-171]

AML-pDC is characterized by AML associated with increased numbers of pDCs in the bone marrow and peripheral blood.[157-159,172] The pDCs show a heterogeneous immunophenotypic profile, including an immature subset expressing CD34, and more mature pDCs with low or no CD56 expression, and frequent negativity or low

expression of TCL1.[157,159,172] Notably, a phenotypic continuum has been observed between myeloid blasts and mature pDCs,[157-159,172] and it is likely that the immature subgroup of BPDCN reported by Martín-Martín et al.[83] corresponds to AML-pDCs.[157] Several mutations have been detected in AML-pDCs, with *RUNX1* occurring in 43 of 57 (75%) cases; the mutations are shared by blasts, pDCs, monocytes and cDCs, suggesting a common differentiation pathway.[157,158]

Various features distinguish AML-pDCs from BPDCN: myeloid blasts are >20% in all patients; skin and extramedullary site involvement is infrequent at onset of the disease; pDCs are heterogeneous, including an immature subset expressing CD34, and a more mature one mostly negative for CD56 and TCL1; and *RUNX1* mutation occurs in the majority of cases, while it has rarely been reported in BPDCN.[105,106]

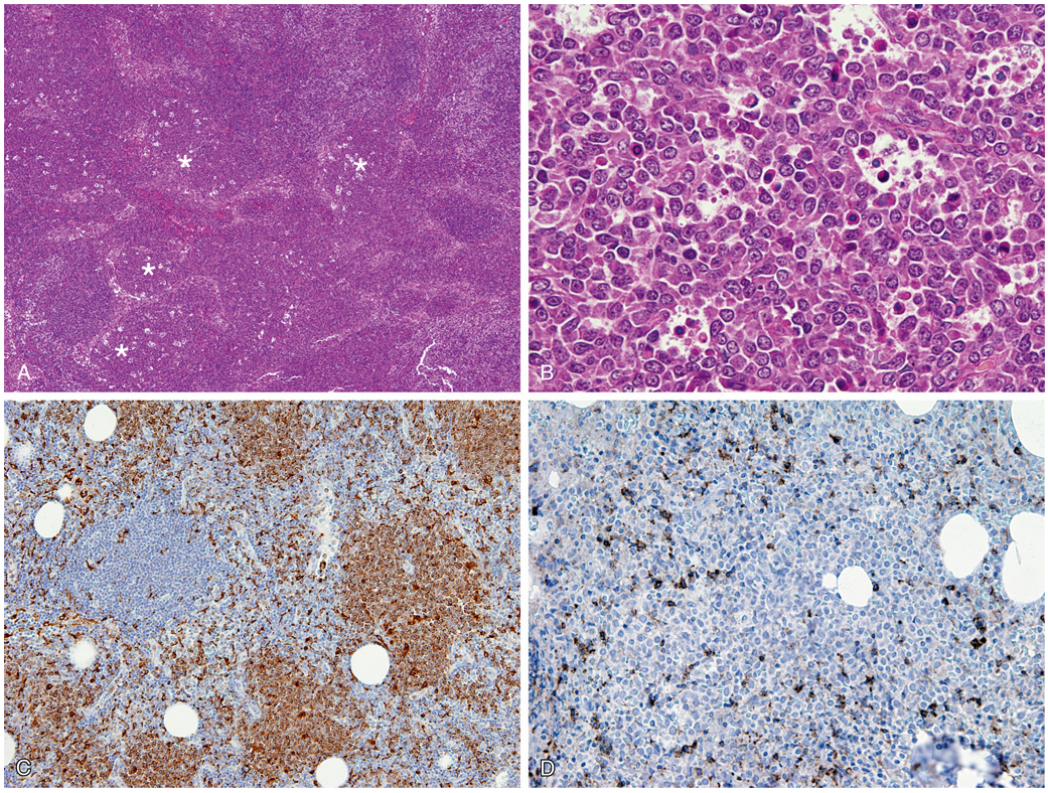

FIGURE 51-6 Mature plasmacytoid dendritic cell proliferation (MPDCP) involving a lymph node in a patient with chronic myelomonocytic leukemia (CMML), showing numerous nodular aggregates of plasmacytoid dendritic cells *(asterisks)* **(A)**. Note the mature morphology of the plasmacytoid dendritic cells (pDCs) and the numerous apoptotic bodies **(B)**. There is strong expression of CD68 **(C)**, while CD56 is negative **(D)**.

Pearls and Pitfalls

- There is no single morphologic feature absolutely distinctive for blastic plasmacytoid dendritic cell neoplasm (BPDCN).
- Consider BPDCN in any infiltrate composed of monotonous medium-sized immature cells, especially involving the skin, bone marrow, or lymph nodes.
- Expression of CD4 and CD56 suggests the diagnosis of BPDCN, but it is not specific and must prompt to extend the phenotypic analysis.
- Plasmacytoid dendritic cell (pDC)–specific markers (e.g., CD123, TCL1, CD303, TCF4) are required for a correct diagnosis.
- The indolent clinical presentation contrasts with the systemic dissemination of the disease and might divert from a prompt diagnosis, leading to delayed and inappropriate treatments.

Interdigitating Dendritic Cell Sarcoma

Follicular Dendritic Cell Sarcoma and Epstein-Barr Virus–Positive Inflammatory Follicular Dendritic Cell/Fibroblastic Reticular Cell Tumor

Non-Neoplastic Histiocytic Disorders

Hemophagocytic Lymphohistiocytosis

Definition

Hemophagocytic lymphohistiocytosis (HLH)[1] is a rare and often lethal condition characterized by immune dysregulation of T cells or natural killer (NK) cells and persistent hypercytokinemia, leading to an exaggerated activation of macrophages that accumulate in organs and tissues and show hemophagocytosis. In the 2016 revised classification of histiocytoses and neoplasms of the macrophage-

dendritic cell lineages,[2] HLH has been classified in the H group, and includes primary or familial HLH (FHLH) arising in the setting of genetic or familial inheritance and accounting for about 25% of cases, and secondary or reactive HLH (SHLH), mostly related to infections, neoplasia, and autoimmunity.

This dichotomous definition of HLH has recently been questioned by the North American Consortium for Histiocytosis (NACHO) because both FHLH and SHLH can be triggered by infections or other immune activating events, and heterozygous or low-penetrance mutations in FHLH-associated genes are involved in the pathogenesis of some forms of SHLH.[3,4]

Epidemiology

HLH is a rare but likely underrecognized disease, occurring in both children and adults, with an increasing incidence. The precise epidemiologic profile of HLH is not well defined. About 25% of cases of HLH are FHLH and typically present in children under 1 year of age. Surveys from Italy, Sweden, and the United States[5-8] have reported an annual incidence of FHLH in 1 to 10 per million children, with a 1:1 male-to-female ratio. In children, genetic defects play a predominant part in the development of HLH, which usually manifests within the first 6 months of life and in rare cases may even develop in utero or at birth. HLH is estimated to occur in the neonatal period at a rate of 1 in 50,000 to 150,000 births.[4] However, cases with late onset up to adulthood have been reported.[5] In about 50% of cases, FHLH occurs in a known familial setting, and in the remaining cases, as a sporadic event.[5] Because of ethnic variations in the causative mutations of FHLH, 47% of White patients have

mutations in *UNC13D,* 22% in *STXBP2,* and 20% in *PRF1,* while *PRF1* mutations occur in 71% and 98% of Hispanic and Black patients, respectively, and in 36% of Arabs.[4]

SHLH may occur at any age,[2] and it is frequently associated with an identifiable predisposition or trigger. A countrywide survey in Japan found an annual incidence of HLH of 1 per 800,000 individuals of all ages, with a male-to-female ratio of 0.94. More than 95% of cases were SHLH and 40% of all HLH cases had associated Epstein-Barr virus (EBV) infection.[9] In a revised series of 775 adults with HLH, the mean age at diagnosis was 49 years, with a male-to-female ratio of 1.7:1.[10] HLH occurring in adults has a significant geographic variability, suggesting a specific genetic background or differences in susceptibility to triggering, especially by infectious agents.[10,11] SHLH occurring in children and young adults is mostly associated with EBV infection, followed by cytomegalovirus (CMV) infection. HLH occurs in about 10% of children with systemic juvenile idiopathic arthritis, especially in early stages of the disease.[4] In adults, disease triggers, especially infections and neoplasms, and, less frequently, autoimmunity, are the main causative factors.[10] The occurrence of HLH in adults has been increasingly recognized over the past decades, especially related to hematologic neoplasms,[10,12] and an underlying malignancy occurs in >50% of adult cases.[13] However, nearly one-third of adult HLH has more than one cause.[10]

Etiology and Pathogenesis

The cellular and molecular mechanisms contributing to the development of HLH are only partially understood, and it is thought that instead of representing one definite disease, HLH consists of

different conditions characterized by a persistent activation of the immune system through different pathways, depending on individual predispositions and variable environmental triggers.[4]

Clinical observations, genetic analysis, and animal models have shown that HLH is primarily driven by an aberrant immune response that does not appear to target self-antigens and can be eventually triggered by infections.[3] In most FHLH variants, the main anomaly is an uncontrolled activation of T cells (especially CD8-positive cytotoxic T cells), with consequent activation of other immune cells, especially macrophages, resulting in a persistent amplification loop where these cells stimulate each other. Interferon gamma (IFN-γ) is a key mediator of disease development, causing an exaggerated inflammatory response with macrophage activation by T cells and hypersecretion of proinflammatory cytokines (e.g., tumor necrosis factor [TNF]-α, interleukin [IL]-1β, IL-6, IL-10, and IL-18).[3,4,10,14,15] Notably, the reciprocal activation of T cells and macrophages is strongly supported by soluble IL-2 receptor (sIL-2R) and soluble hemoglobin-haptoglobin scavenger receptor (CD163), respectively representing a T cell and a macrophage activation marker.[4,16]

Tissue infiltration by activated immune cells and local and systemic effects of the “cytokine storm” are responsible for the development of the main clinical and laboratory features of HLH and contribute to tissue damage, progressive systemic organ failure, and hemophagocytosis.[17]

Primary or Genetic HLH

There are many genetic causes of predisposition to HLH (**Table 52-1**). FHLH clusters around genes (*PRF1, UNC13D, STX11,* and *STXBP2*) whose related molecules are involved in cell-mediated cytotoxicity and lymphocyte activation/survival.

The cause of FHLH type 1 (FHLH1), accounting for approximately 10% of FHLH cases, remains to be elucidated. FHLH type 2 (FHLH2) is caused by perforin deficiency caused by mutation of *PRF1,* which was the first gene reported as a cause of FHLH, accounting for about 30% to 35% of cases.[18] During granule-mediated cytotoxicity, perforin is released from the cytotoxic granules of effector T or NK cells within an immunologic synapse and oligomerizes on target cells, causing the formation of pores through which cytotoxic granule contents enter into the target cell, inducing apoptosis. The perforin and the Fas systems are important in the maintenance of dendritic cell homeostasis and in limiting T-cell activation by antigen presentation, thus controlling the inflammatory response.[19] The deficiency of the cytolytic effector perforin, resulting in absent or scarcely detectable cytotoxic granules in cytotoxic lymphocytes, leads to a pathophysiologic setup for HLH.[17,20] In addition, several unusual missense mutations of the perforin gene have been identified, that result in a mutated protein that is not cytotoxic to the target cell, which may be associated with atypical (late-onset) FHLH.[21] Perforin polymorphism c.272C>T (p.A91V) is also frequently found in late-onset FHLH, and homozygosity for this allele appears to be associated with susceptibility to lymphoma and leukemia.[22,23]

FHLH types 3 to 5 are caused by mutations in *UNC13D, STX11,* and *STXBP2,* respectively.[24-27] These genes encode for protein

products that are critical for normal cytotoxic granule exocytosis, resulting in the lack of granule release into the immunologic synapse and failure to kill target cells. FHLH type 3 accounts for about 30% of FHLH cases[28] and is associated with MUNC13-4 deficiency. In FHLH type 4, patients with mutations in *STX11* encoding syntaxin-11[26] have a worldwide distribution, although the vast majority are of Turkish/Arab descent (accounting for 20% of cases) and show late-onset disease.[26] The most recently identified, FHLH type 5, is caused by mutations in the *STXBP2* gene resulting in deficiency of syntaxin-binding protein 2, also named MUNC18-2.[27]

Pigmentary disorders (Griscelli syndrome type 2, Chediak-Higashi syndrome, and Hermansky-Pudlak syndrome type 2; respectively associated with mutations of *RAB27A, LYST* and *AP3B1*), show widespread compromise of lysosomal granule trafficking that can also affect melanocytes and other cells.[29-31] These disorders share with FHLH the common pathophysiologic mechanism of impaired cytotoxicity responses that lead to the inability of effector lymphocytes to kill infected cells. Remarkably, patients with Hermansky-Pudlak syndrome type 2 have a lower incidence of HLH than other disorders.[20] Because some of the proteins essential for lytic granule secretion by effector lymphocytes are also required for melanocyte trafficking of pigment granules, these disorders are associated with albinism, while their variable involvement in platelet and neutrophil functions also can be responsible for bleeding, neutropenia, and progressive neurodevelopmental abnormalities.[20]

The X-linked lymphoproliferative (XLP) diseases type 1 and 2 are caused by pathologic variants in *SH2D1A* and *XIAP*.[32-35] In XLP1, the consequent functional defect of the encoded protein, SLAM-

associated protein (SAP), leads to defective 2B4-mediated cytotoxicity, especially toward EBV-infected B-cells, lack of invariant NK/T cell development, and resistance to T-cell restimulation-induced cell death, thus impairing the physiologic mechanism of T-cell response downregulation.[36-39]

The HLH occurring in XLP1 patients is almost exclusively associated with EBV infection and can be associated with malignant lymphoproliferation.[40] In XLP2, XIAP deficiency causes dysregulation of NLRP3 inflammasome function with overproduction of inflammatory IL-1β and IL-18.[41] The persistent high levels of IL-18 occurring in these patients likely contributes to the HLH susceptibility.[42] Another mechanism that can contribute to HLH in XIAP deficient patients is related to the direct inhibitory function of XIAP on caspase-3, caspase-7, and caspase-9 affecting regulation of cell death.[39] XIAP-deficient cells, including T cells, are more vulnerable to cell death and the inefficient effector cell function may also contribute to HLH pathogenesis.[35] In XLP2, EBV infection acts as a trigger in 30% to 80% of cases.[43,44] Patients do not develop lymphoma but frequently develop inflammatory bowel disease, hypogammaglobulinemia, recurrent infections, and other more rare complications.[20]

From Canna SW, Marsh RA, Pediatric hemophagocytic lymphohistiocytosis. *Blood*, 2020. 135(16): pp. 1332-1343.

In addition to XLP, there are several primary immunodeficiencies (PIDs) mainly related to mutations of *MAGT1, ITK, CD27, CD70, CTPS1,* and *RASGRP1* genes, in which patients are at high risk of EBV infection, manifesting as severe EBV infection, EBV-HLH, chronic active EBV, and lymphoma (**Table 52-1**).[45]

A unifying process in these HLH conditions associated with EBV infection appears to be the failure to control viral replication in B cells[46,47] during severe primary EBV infection, caused by inability of CD8-positive T cells and NK cells to kill EBV-infected B cells (XLP1), resistance of infected B cells to cytolysis (XLP2), or impaired expansion of EBV-specific T-cell clones in the other genetic diseases with susceptibility to EBV-HLH. In all of these circumstances, persistent viral replication and sustained antigenic stimulation of T cells seems to drive HLH.[47]

Gain-of-function mutations in *NLRC4* and heterozygous mutations in *CDC42* represent other very uncommon genetic conditions predisposing to HLH.[48,49] Mutations of *NLRC4* can be dominantly inherited or happen as de novo germline or even as somatic mutations.[50] These lead to constitutive activation of the

NLRC4 inflammasome, resulting in high blood levels of IL-18, thought to be the main pathogenetic mechanism responsible for the disease, as also supported by the clinical response to recombinant IL-18BP, which decreases IL-18 activity.[51]

Heterozygous mutations of *CDC42* affecting the protein at C-terminal amino acids 186, 188, or 192 cause autoinflammation, including fatal HLH in some cases.[52,53] In addition, neonatal patients show facial dysmorphism, hepatosplenomegaly, recurrent fever, urticaria-like skin rashes, failure to thrive, cytopenias, high transaminases, and elevated inflammatory markers. It has been hypothesized that the *CDC42* mutations interfere with actin assembly, resulting in anomalies in several cell functions (e.g., cytoskeletal rearrangement, cell signaling, polarization, proliferation, migration, and cytotoxicity processes). The very high levels of IL-18 and increased production of IL-1β ex vivo support a dysregulated inflammasome function and the autoinflammatory nature of the disease.[52,53] The pathogenetic role of IL-1β is also supported by clinical response to IL-1β inhibitors.[53]

Numerous inborn errors of metabolism (e.g., multiple sulfatase deficiency, lysosomal acid lipase deficiency/Wolman disease, Gaucher disease [GD], Pearson syndrome, galactosialidosis, Niemann-Pick disease [NPD]) can also present with HLH but are not included in primary HLH. HLH particularly occurs in lysinuric protein intolerance caused by mutations in *SLC7A7*.[20,54] Lack of degradation of substrates results in their accumulation within macrophages and may lead to inflammasome and persistent macrophage activation, with subsequent development of HLH.

Secondary or Reactive Hemophagocytic Lymphohistiocytosis

A number of conditions are associated with SHLH, including viral infections (29%), other infections (20%), malignancies (27%), rheumatologic disorders (7%), immune deficiency syndromes (6%), and drugs.[55]

SHLH is predominantly driven by sustained immune activation rather than by an intrinsic defect in immune functions. The mechanisms leading to impaired host immunity and uncontrolled immune response are multifactorial. These include imbalance between infected cells and immune effector cells, transient immune dysfunction caused by immunosuppressive drugs or low NK-cell numbers, interference with cytotoxic function by viruses or cytokines, and single nucleotide polymorphisms in genes important in the immune response.[56] Notably, hypomorphic mutations in *PRF1, UNC13D,* and *STXBP2* have been found in 14% of adult patients with HLH,[57] suggesting that these mutations likely play a contributing role in development of HLH when patients face immune challenges such as EBV infection, autoimmune disorders, or malignant tumors.

Infection-associated HLH can be a sporadic event, or can be responsible for HLH occurring in other conditions.[4,10] EBV, CMV, and, less frequently, other members of the herpesvirus family are the most commonly reported causes of HLH.[55,58] Other DNA or RNA viruses belonging to different families may be associated with HLH,[55] including parvovirus B19,[59] all types of seasonal, avian, and swine influenza viruses, and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2).[60-62]

Bacteria (*Babesia, Bartonella, Borrelia,* and *Brucella* species, *Coxiella burnetii, Ehrlichia chaffeensis, Leptospira* spp., *Listeria* spp., *Mycoplasma pneumoniae, Mycobacterium avium, Mycobacterium bovis*–weakened form [Bacillus Calmette–Guérin, *Mycobacterium tuberculosis*]), protozoa (especially *Leishmania* spp., *Plasmodium* spp., and *Toxoplasma gondii*), and fungi (*Candida* spp., *Cryptococcus neoformans, Histoplasma capsulatum,* and *Penicillium marneffei*) have also been reported to cause HLH, in both immunocompetent and immunodeficient individuals.[55,63]

EBV triggers HLH, usually in the context of primary infection in young individuals with FHLH and primary immunodeficiency,[46,47] while in adults, HLH mostly depends on virus reactivation in immunocompromised patients.[10] EBV not only infects the B cells but also can infect T cells and NK cells, particularly in SHLH, in which infection of CD8-positive T cells results in a cytokine storm, leading to secondary activation of histiocytes and macrophages.[64] CMV causes HLH in both immunocompetent and immunocompromised patients.[58]

In addition to the genetic settings strongly associated with HLH (**Table 52-1**), HLH may also occur in severe combined immunodeficiency, chronic granulomatous disease, Wiskott-Aldrich syndrome, DiGeorge syndrome, X-linked agammaglobulinemia, and autoimmune lymphoproliferative syndrome (ALPS).[3,20] The host susceptibility to infection and the resulting abnormal immune responses caused by the underlying disease are likely responsible for HLH development, triggered by defective cytolysis during viral infections.[15]

Herpesviruses infections (primary or reactivation in the setting of immunosuppression) are the most common trigger of HLH developing in adults treated with chemotherapy for cancer or immunosuppressive drugs for inflammatory diseases.[3,10] Apart from susceptibility to infections, the pathogenesis of HLH in these conditions may also be related to drug-induced suppression of cytolytic activity.[4]

Patients with chronic human immunodeficiency virus (HIV) and hepatitis virus (B or C) infections can develop HLH during either the acute or chronic phase. In HIV, HLH can be triggered by opportunistic infections, especially intracellular pathogens such as *M. tuberculosis, Pneumocystis jiroveci,* and *Plasmodium* spp., and more rarely by other pathogens, neoplasms, or highly active antiretroviral therapy.[10,15]

HLH developing in patients with malignant neoplasms accounts for 40% to 70% of HLH cases.[12,65] It mainly occurs in adults, where it may complicate up to 1% of tumors,[10,66] but also occurs in infancy. There are a few plausible pathogenic mechanisms in malignancy-associated HLH, such as persistent antigen stimulation and hypersecretion of proinflammatory cytokines by the malignant cells, inherited immune defects such as *HAVCR2* mutation and XLP disease predisposing individuals to both cancer and HLH, and T-cell dysfunction and disruption of immune homeostasis related to cancer-directed therapy.[67] In cases of new onset HLH, it is possible that transformed cells are mainly responsible for HLH by the upregulation of IFN-γ and TNF-α production, especially in the presence of malignancy-associated EBV replication.[4]

Of SHLH occurring in adults, 50% is associated with a hematologic neoplasm. Lymphoma is the most common cause, especially NK-cell and peripheral T-cell lymphoma (35%), followed by B-cell lymphomas (32%), leukemias (6%), and Hodgkin lymphoma (6%).[67-69] Most large case series of lymphoma-associated HLH are from Asian centers, including China and South Korea for T-cell and NK-cell lymphoma, and Japan, where B-cell lymphoma is more prevalent.[67] Notably, HLH was found to have a 26% prevalence in the rare intravascular B-cell lymphoma, especially in Japan, and Asian compared with Western patients.[10,70] Not unexpectedly, HLH is frequently reported in histiocyte disorders,[67] and a retrospective study of HLH in Langerhans cell histiocytosis (LCH) showed a 9.3% 2-year cumulative incidence.[71]

HLH more rarely develops in patients with solid malignancies (3%), which include germ cell tumors, lung, prostate, colon and hepatocellular carcinoma, and neck squamous cell carcinoma.[72] HLH may develop before cancer treatment or during therapy; in the latter case, it is most probably caused by immunosuppression and associated infections.[66,73]

HLH occurring in in the context of rheumatologic disorders is also known as macrophage activation syndrome (MAS) or MAS-HLH.[2] Although MAS and HLH are very similar and should be viewed as the same disease,[3] there are notable differences in presentation, especially related to platelet and neutrophil counts and fibrinogen levels.[74] HLH occurs in approximately 10% of children with severe-onset juvenile idiopathic arthritis (so-JIA),[74] with subclinical presentations in 30% to 40% of cases and lethal complication in 20%.[75,76] In so-JIA, HLH presents at the onset of disease in 22% of

cases and in roughly half of them in the context of active so-JIA without recognizable triggers, while infection and drugs have been associated with HLH in 30% and 4% of cases, respectively.[74] MAS in adults is most commonly seen in adult-onset Still disease (AOSD), reported in 15% up to 20% of cases.[77-79] MAS has also been reported in systemic lupus erythematosus (0.9%–4.6% of cases),[80] Kawasaki disease (1.1%–1.9%),[81] dermatomyositis, and rheumatoid arthritis.[82]

SHLH can be induced by immune-activating therapies for cancer and by drugs responsible for drug-induced hypersensitivity syndrome (DIHS).[4] Similarly to other forms of HLH, therapy-related HLH is likely driven by the aberrant and sustained activation of CD8-positive T cells. Immune checkpoint inhibitor therapies targeting PD-1, PD-L1, or CTLA-4 enhance antitumor T-cell activity, inducing CD8-positive T cell responses, which can result in inflammatory syndromes resembling HLH.[83,84] Similarly, genetically engineered autologous CD8-positive cytotoxic T cells expressing chimeric antigen receptors (CAR-T), especially applied for treating patients with hematologic and solid malignancies, frequently induce the IL-6–driven cytokine release syndrome, which can evolve into HLH.[85-87]

HLH can also be a complication of hematopoietic stem-cell transplantation (HSCT), with higher incidence in recipients of allogeneic HSCT and umbilical cord blood grafts containing mostly naïve T cells.[88-92] Posttransplant HLH can be difficult to diagnose, as clinical and laboratory signs overlap with recovering bone marrow.[55]

HLH occasionally occurs in the context of DIHS,[93] where molecular interactions occur between the drug and human leukocyte

antigen (HLA) proteins encoded by DIHS-associated risk alleles, resulting in hyperstimulation of CD8-positive T cells.[4]

Clinical Features

The clinical features of HLH are widely variable; symptoms can manifest insidiously or arise quickly with critical illness that rapidly evolves into a shocklike clinical state.[4,5,10,15,57] Most patients with HLH are acutely ill and present with high, persistent fevers, multiple organ involvement with hepatosplenomegaly, skin rash, neurologic symptoms, liver dysfunction, and coagulopathy. Lymphadenopathy may occur in HLH, and when extensive or bulky it should prompt exclusion of an underlying lymphoma. Severe liver damage with synthetic dysfunction combined with endothelial activation and disseminated intravascular coagulation cause coagulopathy, with hemorrhage, petechiae, ecchymosis, and purpura.[4] Patients frequently have abdominal pain and non-specific gastrointestinal symptoms (diarrhea, nausea, vomiting, jaundice), or even gastrointestinal hemorrhage and pancreatitis.[10] Severe forms of HLH can involve lungs, heart, and kidney, with signs and symptoms requiring supportive care.[10,94] Central nervous system (CNS) involvement is more common in pediatric HLH, especially with FHLH, where it occurs in about one-third of cases. Symptoms are variable and include seizures, meningismus, ataxia, dysarthria, encephalopathy, and signs of cranial nerve involvement.[95,96] Notably, in rare cases HLH presents with isolated CNS inflammation, with minimal or even no systemic symptoms, thus causing irreparable delay in diagnosis.[97] Posterior reversible

encephalopathy syndrome (PRES) may complicate HLH, particularly FHLH.[98]

HLH is typically associated with multiple laboratory abnormalities and their recognition as a full spectrum is important for diagnosis, since none alone is specific for HLH.[4] Most patients present with or develop a combination of cytopenia, signs of hepatocellular injury, coagulopathy, and in severe cases, biochemical evidence of organ failure. Blood cytopenia with combinations of leukopenia (including neutropenia), anemia, and thrombocytopenia are very frequent in children with HLH, while in adults it can be less severe.[15] Elevated liver aminotransferases occur during the early phases of the disease and often track its activity. The cytokine storm typically driving HLH is associated with high C-reactive protein levels and elevated erythrocyte sedimentation rates (ESR), the latter falling as disease progresses, while coagulation abnormalities (hypofibrinogenemia, elevated D-dimer, and prolonged prothrombin and partial thromboplastin time) increasingly worsen.
